INFECTIOUS DISEASES OF THE FETUS AND NEWBORN INFANT, 7E

**Notice**

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on his or her own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

# Preface

Major advances in biology and medicine made during the past several decades have contributed greatly to our understanding of infections that affect the fetus and newborn. As the medical, social, and economic impact of these infections becomes more fully appreciated, the time is again appropriate for an intensive summation of existing information on this subject. Our goal for the seventh edition of this text is to provide a complete, critical, and contemporary review of this information. We have directed the book to all students of medicine interested in the care and well-being of children, and hope to include among our readers medical students, practicing physicians, microbiologists, and health care workers. We believe the text to be of particular importance for infectious disease specialists; obstetricians and physicians who are responsible for the pregnant woman and her developing fetus; pediatricians and family physicians who care for newborn infants; and primary care physicians, neurologists, audiologists, ophthalmologists, psychologists, and other specialists who are responsible for children who suffer the sequelae of infections acquired in utero or during the first month of life.

The scope of this book encompasses infections of the fetus and newborn, including infections acquired in utero, during the delivery process, and in early infancy. When appropriate, sequelae of these infections that affect older children and adults are included as well. Infection in the adult is described when pertinent to recognition of infection in the pregnant woman and her developing fetus and newborn infant. The first chapter provides an introductory overview of the subsequent chapters, general information, and a report on new developments and new challenges in this area. Each subsequent chapter covers a distinct topic in depth, and when appropriate touches on issues that overlap with the theme of other chapters or refers the reader to those chapters for relevant information. Chapters in Sections II, III, and IV cover specific types of infection, and each includes a review of the history, microbiology, epidemiology, pathogenesis and pathology, clinical signs and symptoms, diagnosis, prognosis, treatment, and prevention of the infection. Chapters in Sections I and V address issues of a more general nature. The length of the chapters varies considerably. In some instances, this variation is related to the available fund of knowledge on the subject; in others (e.g., the chapters on host defense, toxoplasmosis, neonatal diarrhea, varicella, measles, and mumps), the length of the chapter is related to the fact that recent comprehensive reviews of these subjects are not otherwise available.

For J.S.R. and J.O.K., it has been an extraordinary experience and privilege over the past 40 years to be participants in reporting the advances in understanding and management of the infectious diseases of the fetus and newborn infant. Consider the virtual elimination in the developed world of some infectious diseases (e.g., rubella, early-onset group B streptococcal diseases); the recognition of new diseases (e.g., *Borrelia*, HIV); the increased survival and vulnerability to infection of the very low birth weight infant; the introduction of new antimicrobial agents, in particular antiviral and antifungal drugs; and increased emphasis on immunization of women in the childbearing years to prevent transmission of disease to the fetus and neonate. Of particular importance now and in the future is the recognition of the universality of infectious diseases. Of particular concern is the continued high mortality rates of infectious diseases for infants in the first weeks of life. Increased efforts are important to extrapolate advances in care of the pregnant woman and her newborn infant from developed countries to regions with limited resources.

The first, second, third, fourth, fifth, and sixth editions of this text were published in 1976, 1983, 1990, 1995, 2001, and 2006. As of this writing, in summer 2010, it is most interesting to observe the changes that have occurred in the interval since publication of the last edition. New authors provide fresh perspectives. Major revisions of most chapters suggest the importance of new information about infections of the fetus and newborn infant.

Each of the authors of the different chapters is a recognized authority in the field and has made significant contributions to our understanding of infections in the fetus and newborn infant. Most of these authors are individuals whose major investigative efforts on this subject have taken place during the past 25 years. Almost all were supported, in part or totally, during their training period and subsequently, by funds obtained from the National Institutes of Health or from private agencies such as March of Dimes and Bill & Melinda Gates Foundation. The major advances of this period would not have been possible without these funding mechanisms and the freedom given to the investigators to pursue programs of their own choosing. The advances present in this text are also a testimony to the trustees of agencies and the legislators and other federal officials who provided research funds from the 1960s to the present day.

Two of us (J.S.R. and J.O.K.) were Fellows at the Thorndike Memorial Laboratory (Harvard Medical Unit, Boston City Hospital) in the early 1960s under the supervision of Maxwell Finland. Although subsequently we worked in separate areas of investigation on the two coasts, one of us as an internist and the other as a pediatrician, we maintained close contact, and, because of a mutual interest in infections of the fetus and newborn infant and their long-term effects, we joined our efforts

to develop this text. Christopher B. Wilson joined us in editing the sixth and now seventh editions. Chris trained in immunology and infectious diseases in Palo Alto with J.S.R., and since J.S.R. and J.O.K. consider themselves as sons of Maxwell Finland, Chris is representative of the many grandsons and granddaughters of Dr. Finland. Joining us for this edition are two new editors, Yvonne A. Maldonado and Victor Nizet. Bonnie is an expert in pediatric HIV infection and is the Chief of the Division of Pediatric Infectious Diseases at Stanford University School of Medicine. Victor is an expert in the molecular pathogenesis of gram-positive bacterial infections and Chief of the Division of Pharmacology and Drug Discovery in the Departments of Pediatrics and the Skaggs School of Pharmacy and Pharmaceutical Sciences at the University of California, San Diego.

We are indebted to our teachers and associates, and especially to individuals such as Dr. Maxwell Finland, who guided our training and helped to promote our development as physician-scientists through the early stages of our careers. We also wish to express our appreciation to Sarah Myers, and Judith Fletcher, Rachel Miller and Jagannathan Varadarajan of Elsevier, for guiding this project to a successful conclusion, and to Ms. Nancy Greguras for her editorial assistance.

CHAPTER 1

# Current Concepts of Infections of the Fetus and Newborn Infant

**Yvonne A. Maldonado ⚬ Victor Nizet ⚬ Jerome O. Klein ⚬ Jack S. Remington ⚬ Christopher B. Wilson**

CHAPTER OUTLINE

## OVERVIEW

Current concepts of pathogenesis, microbiology, diagnosis, and management of infections of the fetus and newborn infant are briefly reviewed in this chapter. This first section of the book contains chapters providing a global perspective on fetal and neonatal infections and chapters addressing obstetric factors, immunity, host defenses, and the role of human breast milk in fetal and neonatal infections. Chapters containing detailed information about specific bacterial, viral, protozoan, helminthic, and fungal infections follow in subsequent sections. The final section contains chapters addressing nosocomial infections, the diagnosis and therapy of infections in the fetus and neonate, and prevention of fetal and neonatal infections through immunization of the mother or neonate.

Changes continue to occur in the epidemiology, diagnosis, prevention, and management of infectious diseases of the fetus and newborn infant since publication of the last edition of this book. Some of these changes are noted in Table 1–1 and are discussed in this and the relevant chapters.

Substantial progress has been made toward reducing the burden of infectious diseases the fetus and newborn infant. The incidence of early-onset group B streptococcal disease has been reduced by aggressive use of intrapartum chemoprophylaxis and, in particular, by the culture-based chemoprophylaxis strategy now recommended for universal use in the United States. Vertical transmission of human immunodeficiency virus (HIV) has been reduced by identification of the infected mother and subsequent treatment, including the use of brief regimens that are practical in countries with high prevalence but limited resources. There has been a commitment of resources by government agencies and philanthropies, such as the Bill and Melinda Gates Foundation, the Clinton Foundation, Save the Children among others, to combat global infectious diseases in mothers and children. Use of polymerase chain reaction (PCR) techniques in etiologic diagnosis has expanded, permitting more rapid and specific identification of microbial pathogens. Finally, in the United States, national legislation on postpartum length of hospital stay has been enacted to prevent insurers from restricting insurance coverage for hospitalization to less than 48 hours after vaginal deliveries or 96 hours after cesarean deliveries.

Setbacks in initiatives to reduce the global burden of infectious disease in the fetus and newborn infant include the continuing increase in the prevalence of HIV infection in many developing countries, particularly among women, and the lack of finances to provide effective treatment for these women and their newborn infants. In the United States, setbacks include the increase in antimicrobial resistance among nosocomial pathogens and in the incidence of invasive fungal infections among infants of extremely low birth weight.

Use of the Internet has grown further, allowing access to information hitherto unavailable to physicians or parents. Physicians may obtain current information about diseases and management and various guidelines for diagnosis and treatment. Interested parents who have access to the Internet can explore various Internet sites that present a vast array of information and misinformation. As an example of the latter, a case of neonatal tetanus was associated with the use of cosmetic facial clay (Indian Healing Clay) as a dressing on an umbilical cord stump. The product had been publicized as a healing salve by midwives on an Internet site on "cordcare." [1] Because much of the information on the Internet is from commercial sources and parties with varying interests and expertise, physicians should assist interested parents and patients in finding Internet sites of value. Internet sites pertinent to infectious diseases of the fetus and newborn infant are listed in Table 1–2.

DOI: 10.1016/B978-1-4160-6400-8.00001-8

**TABLE 1–1** Changes in Epidemiology and Management of Infectious Diseases of the Fetus and Newborn Infant

| | |
|---|---|
| Epidemiology | Increased viability of very low birth weight infants at risk for invasive infectious diseases |
| | Increased number of multiple births (often of very low birth weight) because of successful techniques for management of infertility |
| | Global perspective of vertically transmitted infectious diseases |
| | Early discharge from the nursery mandated by insurance programs reversed by legislation to ensure adequate observation for infants at risk for sepsis |
| Diagnosis | Polymerase chain reaction assay for diagnosis of infection in mother, fetus, and neonate |
| | Decreased use of fetal blood sampling and chorionic villus sampling for diagnosis of infectious diseases |
| Prevention | Intrapartum antibiotic prophylaxis widely implemented to prevent early-onset group B streptococcal infection |
| | Antiretroviral therapy in pregnancy to prevent transmission of HIV to fetus |
| Treatment | Antiretroviral therapy in mother to treat HIV infection in fetus |
| | Antitoxoplasmosis therapy in mother to treat infection in fetus |
| | Spread within nurseries of multiple antibiotic-resistant bacterial pathogens |
| | Increased use of vancomycin for β-lactam–resistant gram-positive infections |
| | Increased use of acyclovir for infants with suspected herpes simplex infection |

*HIV, human immunodeficiency virus.*

Vital statistics relevant to infectious disease risk in neonates in the United States for 2005 are listed in Table 1–3 [2]. The disparities in birth weight, prenatal care, and neonatal mortality among different racial and ethnic groups are important to note.

The number of infectious diseases in fetuses and newborn infants must be extrapolated from selected studies (see chapters on diseases). Approximately 1% of newborn infants excrete cytomegalovirus (CMV), greater than 4% of infants are born to mothers infected with *Chlamydia trachomatis*, and bacterial sepsis develops in 1 to 4 infants per 1000 live births. Since the institution of intrapartum chemoprophylaxis in the United States, the number of infants with early-onset group B streptococcal disease has declined, with reduction in incidence from approximately 1.5 cases to 0.34 case per 1000 live births, and the incidence is expected to decline further with the universal adoption of the culture-based strategy [3,4]. In the United States, the use of maternal highly active antiretroviral treatment and peripartum chemoprophylaxis has led to a reduction in the rate of mother-to-child transmission of HIV from approximately 25% of infants born to mothers who received no treatment to 2%; less complex but practical regimens of intrapartum prophylaxis have helped to reduce the rate of HIV transmission in the developing world [5–7]. Among sexually transmitted diseases, the rate of congenital syphilis had declined substantially in the United States to 13.4 per 100,000 live births in 2000 [8]; however, after 14 years of decline, the rate of congenital syphilis increased in 2006 and 2007 from 9.3 to 10.5 cases per 100,000 live births, in parallel to the increase in the syphilis rates among the general population [9]. Immunization has virtually eliminated congenital rubella syndrome in newborn infants of mothers who were themselves born in the United States, but cases continue to occur in infants of foreign-born mothers; 24 of 26 infants with congenital rubella born between 1997 and 1999 were born to foreign-born mothers, and 21 of these were born to Hispanic mothers [10]. Efforts led by the Pan American Health Organization to eliminate congenital rubella syndrome in the Americas by 2010 may be successful [11].

Consequences of perinatal infections vary depending on whether the infection occurs in utero or during the intrapartum or postpartum periods. Infection acquired in utero can result in resorption of the embryo, abortion, stillbirth, malformation, intrauterine growth restriction, prematurity, or the untoward sequelae of chronic postnatal infection. Infection acquired during the intrapartum or early postpartum period may result in severe systemic disease that leads to death or persistent postnatal infection. In utero infection and intrapartum infections may lead to late-onset disease. The infection may not be apparent at birth, but may manifest with signs of disease weeks, months, or years later, as exemplified by chorioretinitis of *Toxoplasma gondii* infection, hearing loss of rubella, and immunologic defects that result from HIV infection. The immediate and the long-term effects of these infections constitute a major problem throughout the world.

# INFECTIONS OF THE FETUS

## PATHOGENESIS

Pregnant women not only are exposed to infections prevalent in the community, but also are likely to reside with young children or to associate with groups of young children, which represents a significant additional factor in exposure to infectious agents. Most infections in pregnant women affect the upper respiratory and gastrointestinal

**TABLE 1–3** Vital Statistics Relevant to Newborn Health in the United States in 2005*

tracts, and either resolve spontaneously without therapy or are readily treated with antimicrobial agents. Such infections usually remain localized and have no effect on the developing fetus. The infecting organism may invade the bloodstream, however, and subsequently infect the placenta and fetus.

Successful pregnancy is a unique example of immunologic tolerance—the mother must be tolerant of her allogeneic fetus (and vice versa). The basis for maternal-fetal tolerance is not completely understood, but is known to reflect local modifications of host defenses at the maternal-fetal interface and more global changes in immunologic competence in the mother. Specific factors acting locally in the placenta include indoleamine 2,3-dioxygenase, which suppresses cell–mediated immunity by catabolizing the essential amino acid tryptophan, and regulatory proteins that prevent complement activation [12,13]. As pregnancy progresses, a general shift from T helper type 1 ($T_H1$) cell–mediated immunity to T helper type 2 ($T_H2$) responses also occurs in the mother, although this description probably constitutes an overly simplistic view of more complex immunoregulatory changes [14,15]. Nonetheless, because $T_H1$ cell-mediated immunity is important in host defense against intracellular pathogens, the $T_H2$ bias established during normal gestation may compromise successful immunity against organisms such as *T. gondii*. In addition, it has been proposed that a strong curative $T_H1$ response against an organism may overcome the protective $T_H2$ cytokines at the maternal-fetal interface, resulting in fetal loss.

Transplacental spread and invasion of the bloodstream after maternal infection is the usual route by which the fetus becomes infected. Uncommonly, the fetus may be infected by extension of infection in adjacent tissues and organs, including the peritoneum and the genitalia, during parturition, or as a result of invasive methods for the diagnosis and therapy of fetal disorders, such as the use of monitors, sampling of fetal blood, and intrauterine transfusion.

Microorganisms of concern are listed in Table 1–4 and include those identified in the acronym *TORCH*: *T. gondii*, rubella virus, CMV, and herpes simplex virus (HSV) (as a point of historical interest, the *O* in TORCH originally stood for "other infections/pathogens," reflecting an early appreciation of this possibility). A new acronym is needed to include other, well-described causes of in utero infection: syphilis, enteroviruses, varicella-zoster virus (VZV), HIV, Lyme disease (*Borrelia burgdorferi*), and parvovirus. In certain geographic areas, *Plasmodium* and *Trypanosoma cruzi* are responsible for in utero infections. *ToRCHES CLAP* (see Table 1–4) is an inclusive acronym. Case reports indicate other organisms that are unusual causes of infections transmitted by a pregnant woman to her fetus, including *Brucella melitensis* [16], *Coxiella burnetii* (Q fever) [17], *Babesia microti* (babesiosis) [18], human T-cell

lymphotropic virus types I and II (although the main route of transmission of these viruses is through breast-feeding) [19,20], hepatitis G and TT viruses [21,22], human herpesvirus 6 [23,24], and dengue [25].

Before rupture of fetal membranes, organisms in the genital tract may invade the amniotic fluid and produce infection of the fetus. These organisms can invade the fetus through microscopic defects in the membranes, particularly in devitalized areas overlying the cervical os. It also is possible that microorganisms gain access to the fetus from descending infection through the fallopian tubes in women with salpingitis or peritonitis, or from direct extension of an infection in the uterus, such as myometrial abscess or cellulitis. Available evidence does not suggest, however, that transtubal or transmyometrial passage of microbial agents is a significant route of fetal infection.

Invasive techniques that have been developed for in utero diagnosis and therapy are potential sources of infection for the fetus. Abscesses have been observed in infants who had scalp punctures for fetal blood sampling or electrocardiographic electrodes attached to their scalps. Osteomyelitis of the skull and streptococcal sepsis have followed local infection at the site of a fetal monitoring electrode [26]; HSV infections at the fetal scalp electrode site also have been reported. Intrauterine transfusion for severe erythroblastosis diagnosed in utero also has resulted in infection of the fetus. In one case, CMV infection reportedly resulted from intrauterine transfusion [27]; in another instance, contamination of donor blood with a gram-negative coccobacillus, *Acinetobacter calcoaceticus*, led to an acute placentitis and subsequent fetal bacteremia [28].

Fetal infection in the absence of rupture of internal membranes usually occurs transplacentally after invasion of the maternal bloodstream. Microorganisms in the blood may be carried within white blood cells or attached to erythrocytes, or they may be present independent of cellular elements.

## Microbial Invasion of the Maternal Bloodstream

The potential consequences of invasion of the mother's bloodstream by microorganisms or their products (Fig. 1–1) include (1) placental infection without infection of the fetus, (2) fetal infection without infection of the placenta, (3) absence of fetal and placental infection, and (4) infection of placenta and fetus.

### *Placental Infection without Infection of the Fetus*

After reaching the intervillous spaces on the maternal side of the placenta, organisms can remain localized in the placenta without affecting the fetus. Evidence that placentitis can occur independently of fetal involvement has been

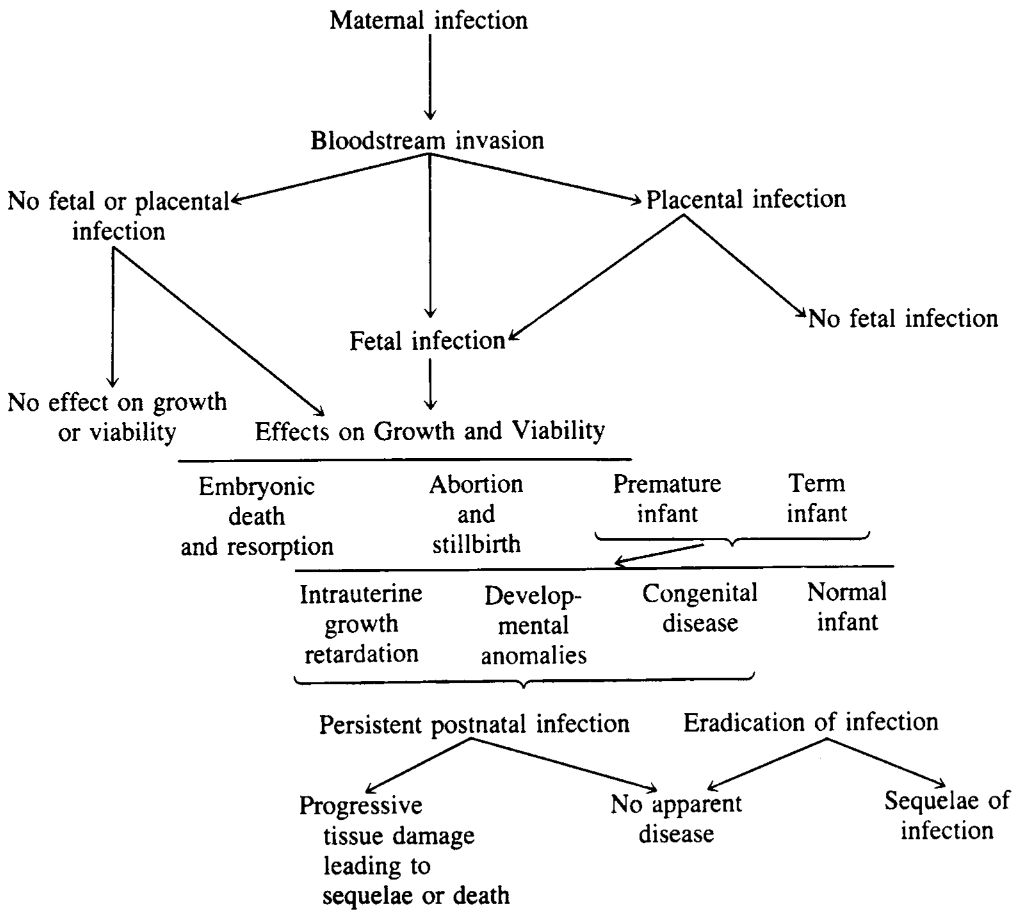

**FIGURE 1–1** Pathogenesis of hematogenous transplacental infections.

shown after maternal tuberculosis, syphilis, malaria, coccidioidomycosis, CMV, rubella virus, and mumps vaccine virus infection. The reasons for the lack of spread to the fetus after placental infection are unknown. Defenses of the fetus that may operate after placental infection include the villous trophoblast, placental macrophages, and locally produced immune factors such as antibodies and cytokines.

### Fetal Infection without Infection of the Placenta

Microorganisms may traverse the chorionic villi directly through pinocytosis, placental leaks, or diapedesis of infected maternal leukocytes and erythrocytes. Careful histologic studies usually reveal areas of placentitis sufficient to serve as a source of fetal infection, however.

### Absence of Fetal and Placental Infection

Invasion of the bloodstream by microorganisms is common in pregnant women, yet in most cases neither fetal nor placental infection results. Bacteremia may accompany abscesses or cellulitis, bacterial pneumonia, pyelonephritis, appendicitis, endocarditis, or other pyogenic infections; nevertheless, placental or fetal infection as a consequence of such bacteremias is rare. In most cases, the fetus is likely protected through efficient clearance of microbes by the maternal reticuloendothelial system and circulating leukocytes.

Many bacterial diseases of the pregnant woman, including typhoid fever, pneumonia, sepsis caused by gram-negative bacteria, and urinary tract infections, may affect the developing fetus without direct microbial invasion of the placenta or fetal tissues. Similarly, protozoal infection in the mother, such as malaria, and systemic viral infections, including varicella, variola, and measles, also may affect the fetus indirectly. Fever, anoxia, circulating toxins, or metabolic derangements in the mother concomitant with these infections can affect the pregnancy, possibly resulting in abortion, stillbirth, and premature delivery.

The effects of microbial toxins on the developing fetus are uncertain. The fetus may be adversely affected by toxic shock in the mother secondary to *Staphylococcus aureus* or *Streptococcus pyogenes* infection. Botulism in pregnant women has not been associated with disease in infants [29,30]. A unique case of Guillain-Barré syndrome in mother and child shows that infection-induced, antibody-mediated autoimmune disease in the mother may be transmitted to her infant. In this case, the disease was diagnosed in the mother during week 29 of pregnancy. A healthy infant was delivered vaginally at 38 weeks of gestation, while the mother was quadriplegic and on respiratory support. On day 12 of life, the infant developed flaccid paralysis of all limbs with absence of deep tendon reflexes, and cerebrospinal fluid (CSF) examination revealed increased protein concentration without white blood cells [31]. The delay in onset of paralysis in the infant seemed to reflect transplacentally transferred blocking antibodies specifically directed at epitopes of the mature, but not the fetal, neuromuscular junction. The infant improved after administration of intravenous immunoglobulin [32].

The association of maternal urinary tract infection with premature delivery and low birth weight is a well-studied example of a maternal infection that adversely affects growth and development of the fetus, despite no evidence of fetal or placental infection. Asymptomatic bacteriuria in pregnancy has been linked to increased numbers of infants with low birth weight [33,34]. In one early study, when the bacteriuria was eliminated by appropriate antibiotic therapy, the incidence of pyelonephritis was lower in the women who received treatment, yet the rate of premature and low birth weight infants was the same among the women in the treatment group as among women without bacteriuria [35]. A meta-analysis concluded that antibiotic treatment is effective in reducing the risk of pyelonephritis in pregnancy and the risk for preterm delivery, although the evidence supporting this latter conclusion is not as strong [36]. The basis for the premature delivery and low birth weight of infants of mothers with bacteriuria remains obscure [37].

### Infection of Placenta and Fetus

Microorganisms may be disseminated from the infected placenta to the fetal bloodstream through infected emboli of necrotic chorionic tissues, or through direct extension of placental infection to the fetal membranes with secondary amniotic fluid infection and aspiration by the fetus.

## Infection of the Embryo and Fetus

Hematogenous transplacental spread may result in death and resorption of the embryo, abortion and stillbirth of the fetus, and live birth of a premature or term infant who may or may not be healthy. The effects of fetal infection may appear in a live-born infant as low birth weight (resulting from intrauterine growth restriction), developmental anomalies, congenital disease, or none of these. Infection acquired in utero may persist after birth and cause significant abnormalities in growth and development that may be apparent soon after birth or may not be recognized for months or years. The variability of the effects of fetal infection is emphasized by reports of biovular twin pregnancies that produced one severely damaged infant and one infant with minimal or no detectable abnormalities [38–43].

### Embryonic Death and Resorption

Various organisms may infect the pregnant woman in the first few weeks of gestation and cause death and resorption of the embryo. Because loss of the embryo usually occurs before the woman realizes she is pregnant or seeks medical attention, it is difficult to estimate the incidence of this outcome for any single infectious agent. The incidence of early pregnancy loss after implantation from all causes has been estimated to be 31%. The proportion of cases of loss because of infection is unknown [44].

### Abortion and Stillbirth

The earliest recognizable effects of fetal infection are seen after 6 to 8 weeks of pregnancy and include abortion and stillbirth. Intrauterine death may result from overwhelming fetal infection, or the microorganisms may interfere

with organogenesis to such an extent that the development of functions necessary for continued viability is interrupted. The precise mechanisms responsible for early spontaneous termination of pregnancy are unknown; in many cases, it is difficult to ascertain whether fetal death caused or resulted from the expulsion of the fetus.

Numerous modifying factors probably determine the ultimate consequence of intrauterine infection, including virulence or tissue tropism of the microorganisms, stage of pregnancy, associated placental damage, and severity of the maternal illness. Primary infection is likely to have a more important effect on the fetus than recurrent infection [45]. Recurrent maternal CMV infection is less severe than primary infection and is significantly less likely to result in congenital CMV infection of the fetus. Available studies do not distinguish between the direct effect of the microorganisms on the developing fetus and the possibility of an indirect effect attributable to illness or poor health of the mother.

### Prematurity

Prematurity is defined as the birth of a viable infant before week 37 of gestation. Premature birth may result from almost any agent capable of establishing fetal infection during the last trimester of pregnancy. Many microorganisms commonly responsible for prematurity are also implicated as significant causes of stillbirth and abortion (Table 1–5).

Previous studies have shown that women in premature labor with bacteria-positive amniotic fluid cultures have elevated levels of multiple proinflammatory cytokines in their amniotic fluid [46–51]. In many patients with elevated levels of interleukin-6 (IL-6), results of amniotic fluid culture were negative. Premature births are invariably observed, however, in women in premature labor having positive amniotic fluid culture and elevated amniotic fluid levels of IL-6.

To clarify further the role of elevated levels of IL-6 in amniotic fluid, Hitti and colleagues [47] amplified bacterial 16S recombinant RNA (rRNA) encoding DNA by PCR to detect infection in amniotic fluid in women in premature labor whose membranes were intact. In patients who were culture-negative by amniotic fluid testing, PCR assay detected bacterial infection in significantly more patients with elevated IL-6 levels. These data suggest that 33% of women in premature labor with culture-negative amniotic fluid but with elevated IL-6 levels may have infected amniotic fluid. The investigators concluded that the association between infected amniotic

fluid and premature labor may be underestimated on the basis of amniotic fluid cultures. They suggested that the broad-spectrum bacterial 16S rDNA PCR assay may be useful for detecting infection of amniotic fluid. Even in cases in which cultures and PCR assay have failed to detect infection, elevated levels of amniotic fluid IL-6 are clearly associated with an increased risk of preterm delivery [52]. Although this finding likely reflects infection undetected by either technique, it is possible that factors other than infection contribute to preterm labor and elevated amniotic fluid IL-6 levels.

### Intrauterine Growth Restriction and Low Birth Weight

Infection of the fetus may result in birth of an infant who is small for gestational age. Although many maternal infections are associated with low birth weight infants and infants who are small for gestational age, causal evidence is sufficient only for congenital rubella, VZV infection, toxoplasmosis, and CMV infection.

The organs of infants dying with congenital rubella syndrome or congenital CMV infection contain reduced numbers of morphologically normal cells [53,54]. By contrast, in infants who are small for gestational age with growth deficit from noninfectious causes, such as maternal toxemia or placental abnormalities, the parenchymal cells are normal in number, but have a reduced amount of cytoplasm, presumably because of fetal malnutrition [55,56].

### Developmental Anomalies and Teratogenesis

CMV, rubella virus, and VZV cause developmental anomalies in the human fetus. Coxsackieviruses B3 and B4 have been associated with congenital heart disease. Although the pathogenetic mechanisms responsible for fetal abnormalities produced by most infectious agents remain obscure, histologic studies of abortuses and congenitally infected infants have suggested that some viruses render these effects through mediating cell death, alterations in cell growth, or chromosomal damage. Lesions resulting indirectly from the microorganisms through inflammatory activation must be distinguished from defects that arise from a direct effect of the organisms on cell and tissue growth in the developing embryo or fetus. Inflammation and tissue destruction, rather than teratogenic activity, seem to be responsible for the widespread structural abnormalities characteristic of congenital syphilis, transplacental HSV and VZV infection, and toxoplasmosis. Infants with congenital toxoplasmosis may have microcephaly, hydrocephalus, or microphthalmia, but these manifestations usually result from an intense necrotizing process involving numerous organisms and are more appropriately defined as lesions of congenital infection, rather than as effects of teratogenic activity of the organism.

Some mycoplasmas [57] and viruses [58,59] produce chromosomal damage in circulating human lymphocytes or in human cells in tissue culture. The relationship of these genetic aberrations to the production of congenital abnormalities in the fetus is unknown.

### Congenital Disease

Clinical evidence of intrauterine infections, resulting from tissue damage or secondary physiologic changes caused by the invading organisms, may be present at birth or may manifest soon thereafter or years later. The clinical manifestations of infection acquired in utero or at delivery in the newborn infant are summarized in Table 1–6. Signs of widely disseminated infection may be evident during the neonatal period in infants with congenital rubella; toxoplasmosis; syphilis; or congenital CMV, HSV, or enterovirus infection. These signs include jaundice, hepatosplenomegaly, and pneumonia, each of which reflects lesions caused by microbial invasion and proliferation, rather than by defects in organogenesis. Although these signs of congenital infection are not detected until the neonatal period, the pathologic processes responsible for their occurrence have been progressing for weeks or months before delivery. In some infants, the constellation of signs is sufficient to suggest the likely congenital infection (Table 1–7). In other infants, the signs are transient and self-limited and resolve as neonatal defense mechanisms control the spread of the microbial agent and tissue destruction. If damage is severe and widespread at the time of delivery, the infant is likely to die.

It is frequently difficult to determine whether the infection in the newborn infant was acquired in utero, intrapartum, or postpartum. If the onset of clinical signs after birth occurs within the minimal incubation period for the disease (e.g., 3 days for enteroviruses, 10 days for VZV and rubella viruses), it is likely that the infection was acquired before delivery. The interval between malaria exposure in the mother and congenital malaria in the infant can be prolonged; one case of congenital malaria resulting from *Plasmodium malariae* occurred in an infant born in the United States 25 years after the mother had emigrated from China [60]. Children with perinatal HIV infection can be diagnosed by 6 months of age using a DNA (or RNA) PCR method, which has largely replaced other approaches for viral detection [61]. A variable fraction (less than half) of children with perinatal HIV contract the infection in utero, depending on the setting and maternal treatment [62]. Virus-negative infants who later become virus-positive may have been infected in the intrapartum or early postpartum period.

### Healthy Infants

Most newborn infants infected in utero by rubella virus, *T. gondii*, CMV, HIV, or *Treponema pallidum* have no signs of congenital disease. Fetal infection by a limited inoculum of organisms or with a strain of low virulence or pathologic potential may underlie this low incidence of clinical disease in infected infants. Alternatively, gestational age may be the most important factor in determining the ultimate consequences of prenatal infection. When congenital rubella and toxoplasmosis are acquired during the last trimester of pregnancy, the incidence of clinical disease in the infected infants is lower than when microbial invasion occurs during the first or second trimester. Congenital syphilis results from exposure during the second or third, but not the first, trimester.

Absence of clinically apparent disease in the newborn may be misleading. Careful observation of infected but healthy-appearing children over months or years often reveals defects that were not apparent at birth. The failure to recognize such defects early in life may be due to the inability to test young infants for the sensory and developmental functions involved. Hearing defects identified years after birth may be the only manifestation of congenital rubella. Significant sensorineural deafness and other central nervous system deficiencies have affected children with congenital CMV infection who were considered to be normal during the neonatal period. In utero infection with *Toxoplasma*, rubella, and CMV may have manifestations that are difficult to recognize, including failure to thrive, visual defects, and minimal to severe brain dysfunction (including motor, learning, language, and behavioral disorders). Infants infected with HIV are usually asymptomatic at birth and for the first few months of life. The median age of onset for signs of congenital HIV infection is approximately 3 years, but many children remain asymptomatic for more than 5 years. Signs of perinatal infection related to HIV include failure to

thrive, persistent diarrhea, recurrent suppurative infections, and diseases associated with opportunistic infections that occur weeks to months or years after birth. Of particular concern is a report by Wilson and colleagues [63] showing stigmata of congenital *T. gondii* infection, including chorioretinitis and blindness, in almost all of 24 children at follow-up evaluations; the children had serologic evidence of infection, but were without apparent signs of disease at birth and did not receive treatment or received inadequate treatment.

Because abnormalities may become obvious only as the child develops and fails to reach appropriate physiologic or developmental milestones, it is crucial to perform careful and thorough follow-up examinations to infants born to women with known or suspected infections during pregnancy.

### *Persistent Postnatal Infection*

Microbial agents may continue to survive and replicate in tissues for months or years after in utero infection. Rubella virus and CMV have been isolated from various body fluid and tissue compartments over long periods from healthy-appearing children and children with abnormalities at birth. Progressive tissue destruction has been shown in some congenital infections, including rubella; toxoplasmosis; syphilis; tuberculosis; malaria; and CMV, HSV, and HIV infection. Recurrent skin and eye infections can occur as a result of HSV infection acquired in utero or at the time of delivery. A progressive encephalitis occurred in children with congenital rubella infection; stable clinical manifestations of congenital infection over many years was followed by deterioration of motor and mental functions at ages 11 to 14 years [64,65]. Rubella virus was subsequently isolated from the brain biopsy specimen of a 12-year-old child. Finally, fetal parvovirus B19 infection can persist for months after birth with persistent anemia because of suppressed hematopoiesis [66].

The mechanisms responsible for maintaining or terminating chronic fetal and postnatal infections are only partially understood. Humoral immune responses, as determined by measurement of either fetal IgM antibodies or specific IgG antibodies that develop in the neonatal period, seem to be intact in almost all infants (see Chapter 4). The importance of cell-mediated immunity, cytokines, complement, and other host defense mechanisms remains to be defined; at present, there is insufficient evidence to support a causal relationship between deficiencies in any one of these factors and persistent postnatal infection. All of the diseases associated with persistent postnatal infection—with the exception of rubella, but including syphilis; tuberculosis; malaria; toxoplasmosis; hepatitis; and CMV, HSV, VZV, and HIV infections—can also produce prolonged and, in certain instances, lifelong infection when acquired later in life.

## EFFICIENCY OF TRANSMISSION OF MICROORGANISMS FROM MOTHER TO FETUS

The efficiency of transmission from the infected, immunocompetent mother to the fetus varies among microbial agents and can vary with the trimester of pregnancy. In utero transmission of rubella virus and *T. gondii* occurs mainly during primary infection, whereas in utero transmission of CMV, HIV, and *T. pallidum* can occur in consecutive pregnancies. The risk of congenital rubella infection in fetuses of mothers with symptomatic rubella was high in the first trimester (90% before 11 weeks of gestation), declined to a nadir of 25% at 23 to 26 weeks, and then increased to 67% after 31 weeks. Infection in the first 11 weeks of gestation was uniformly teratogenic, whereas no birth defects occurred in infants infected after 16 weeks of gestation [67]. By contrast, the frequency of stillbirth and clinical and subclinical congenital *T. gondii* infection among offspring of women who acquired the infection during pregnancy was lowest in the first trimester (14%), increased in the second trimester (29%), and was highest in the third trimester (59%) [68].

Congenital CMV infection results from primary and recurrent infections. On the basis of studies in Birmingham, Alabama, and other centers, Whitley and Stagno and their colleagues [69,70] estimate that 1% to 4% of women have primary infection during pregnancy, 40% of these women transmit the infection to their fetuses, and 5% to 15% of the infants have signs of CMV disease. Congenital infection as a result of recurrent CMV infection occurs in 0.5% to 1% of live births, but less than 1% of the infected infants have clinically apparent congenital disease.

The transmission rate of HIV infection from an untreated mother to the fetus is estimated to be about 25%, but the data are insufficient to identify efficiency of transmission by trimester. Risk of transmission does not seem to be greater in mothers who acquire primary infection during pregnancy than in mothers who were infected before they became pregnant [71].

## DIAGNOSIS OF INFECTION IN THE PREGNANT WOMAN

### Clinical Diagnosis

### *Symptomatic or Clinical Infection*

In many instances, infection in the pregnant woman and congenital infection in the newborn infant can be suspected on the basis of clinical signs or symptoms. Careful examination can be sufficient to suggest a specific diagnosis, particularly when typical clinical findings are accompanied by a well-documented history of exposure (see Tables 1–6 and 1–7).

### *Asymptomatic or Subclinical Infection*

Many infectious diseases with serious consequences for the fetus are difficult or impossible to diagnose in the mother solely on clinical grounds. Asymptomatic or subclinical infections may be caused by rubella virus, CMV, *T. gondii*, *T. pallidum*, HSV, and HIV. Most women infected with these organisms during pregnancy have no apparent signs of disease; only 50% of women infected with rubella virus have a rash, and although occasional cases of CMV mononucleosis are recognized, these constitute a very small proportion of women who acquire primary CMV infection during pregnancy. Similarly, the number of women with clinical manifestations of

toxoplasmosis is less than 10%, and few women have systemic illness associated with primary HSV infection. The genital lesions associated with HSV infection and syphilis often are not recognized.

### Recurrent and Chronic Infection

Some microorganisms can infect a susceptible person more than once, and when such reinfections occur in a pregnant woman, the organism can affect the fetus. These reinfections generally are associated with waning host immunity, but low levels of circulating antibodies may be detectable. Such specific antibodies would be expected to provide some protection against hematogenous spread and transplacental infection. Fetal disease has followed reexposure of immune mothers, however, to vaccinia [72], variola [73], and rubella [74] viruses.

In addition, an agent capable of persisting in the mother as a chronic asymptomatic infection could infect the fetus long after the initial infection. Such delayed infection is common for congenital CMV and HIV infections, which have been observed in infants from consecutive pregnancies in the same mother. Reports of infection of the fetus as a result of chronic maternal infection have been cited in cases of malaria [75], syphilis [76], hepatitis [77], herpes zoster [43] and herpes simplex [78], and *T. gondii* infection [79]. In the case of *T. gondii*, congenital transmission from a chronically infected woman occurs almost solely when the woman is immunocompromised during pregnancy.

### Preconceptional Infection

The occurrence of acute infection immediately before conception may result in infection of the fetus, and the association may go unrecognized. Congenital rubella has occurred in the fetus in cases in which the mother was infected 3 weeks to 3 months before conception. A prolonged viremia or persistence of virus in the maternal tissues may be responsible for infection of the embryo or fetus. The same has occurred rarely in cases of maternal infection with *T. gondii* [80].

## Isolation and Identification of Infectious Agents

### General Approach

Diagnostic tests for microorganisms or infectious diseases are part of routine obstetric care; special care is warranted for selected patients with known or suspected exposure to the infectious agent or clinical signs of infection. Table 1–8 lists diagnostic tests and interventions that may be required in the event of a diagnosis. The specific interventions for each disease are discussed in subsequent chapters.

The most direct mode of diagnosis is isolation of the microbial agent from tissues and body fluids such as blood, CSF, or urine. Isolation of the agent must be considered in context with its epidemiology and natural history in the host. Isolation of an enterovirus from stool during the summer months may represent colonization, rather than significant infection, with risk of hematogenous spread to

**TABLE 1–8** Management of Infections in the Pregnant Woman

| Microorganism | Diagnostic Test | First Visit | Third Trimester | At Delivery | Intervention* |
|---|---|---|---|---|---|
| ***Routine Care*** | | | | | |
| *Mycobacterium tuberculosis* | Tuberculin skin test | + | | | Therapy |
| Gonorrhea | Culture or antigen | + | + | | Therapy |

the fetus. Isolation of an enterovirus from an atypical body fluid or identification of a significant increase in antibody titer would be necessary to define an acute infectious process.

Tests for the presence of hepatitis B virus (HBV) surface antigen (HBsAg) should be performed in all pregnant women. The Centers for Disease Control and Prevention (CDC) has estimated that 16,500 births occur each year in the United States to women who are positive for HBsAg. Infants born to HBsAg-positive mothers may have a 90% chance of acquiring perinatal HBV infection. If maternal infection is identified soon after birth, use of hepatitis B immunoglobulin combined with hepatitis B vaccine is an effective mode of prevention of infection. For these reasons, the Advisory Committee on Immunization Practices of the U.S. Public Health Service [81] and the American Academy of Pediatrics [82] recommend universal screening of all pregnant women for HBsAg.

Because the amniotic fluid contains viruses or bacteria shed from the placenta, skin, urine, or tracheal fluid of the infected fetus, this fluid, which can be obtained during gestation with less risk than fetal blood sampling, may also be used to detect the infecting organism by culture, antigen detection test, or PCR assay. Amniocentesis and analysis of desquamated fetal cells in the amniotic fluid have been used for the early diagnosis of genetic disorders for some time. The seminal publication by Daffos and colleagues in 1983 [83], in which fetal blood sampling for prenatal diagnosis was first described, provided a method for diagnosing various infections in the fetus that previously could be diagnosed only after birth. Their methods were widely adopted and have contributed significantly to our understanding of the immune response of the fetus to various pathogens, including rubella virus, VZV, CMV, and *T. gondii* [84–87], and to a more objective approach to treating infection in the fetus before birth.

Fetal blood sampling and amniocentesis are performed under ultrasound guidance. The method is not free of risk; amniocentesis alone carries a risk of fetal injury or death of 1% [50,88], and fetal blood sampling carries a risk of approximately 1.4% [89]. Amniotic fluid may be examined for the presence of the infecting organism or its antigens, DNA, or RNA. Fetal blood can be examined for the same factors and antibodies formed by the fetus against the pathogen (e.g., IgA or IgM antibodies that do not normally cross the placental barrier). Fetal blood sampling is usually performed during or after week 18 of gestation. A fetus diagnosed with infection with a specific pathogen or who is at high risk for infection (e.g., the fetus of a nonimmune woman who acquired infection with *T. gondii* or rubella virus during pregnancy) may be followed by ultrasound examination to detect abnormalities such as dilation of the cerebral ventricles.

### Isolation, Culture, and Polymerase Chain Reaction Assay

Isolation of CMV and rubella virus [90] and demonstration of HBsAg [91] from amniotic fluid obtained by amniocentesis have been reported. As PCR techniques have proved to be sensitive and specific for diagnosing many infections in the pregnant woman, fetus, and newborn, in many instances isolating the infectious agent to make a definitive diagnosis is no longer necessary with use of PCR techniques. PCR methods decrease the time to diagnosis and increase the sensitivity for diagnosis of many infectious agents, as exemplified by the prenatal diagnosis of infections caused by parvovirus [92,93], CMV [94–96], *T. gondii* [97,98], and rubella virus [99,100].

As with all diagnostic testing, caution is required in interpreting the results of prenatal PCR testing, however, because the sensitivity of PCR results on amniotic fluid is uncertain. One third of cases of congenital toxoplasmosis yield a negative result on amniotic fluid PCR assay [98,100], and infants with congenital rubella may have negative amniotic fluid PCR assay results, but positive fetal blood tests. Also, false-positive rates of 5% for viral DNA detection in fluids obtained for genetic testing have been observed when congenital fetal infection was not suspected or documented. Combined diagnostic approaches in which PCR is used in concert with fetal serology and other diagnostic modalities (e.g., serial fetal ultrasonography) to test amniotic fluid and fetal blood may offer the greatest sensitivity and predictive power in cases in which congenital infection is suspected and this information is important in management decisions [98,101].

### Cytologic and Histologic Diagnosis

Review of cytologic preparations and tissue sections may provide a presumptive diagnosis of certain infections. Cervicovaginal smears or cell scrapings from the base of vesicles are valuable in diagnosing VZV and HSV infections. Typical changes include multinucleated giant cells and intranuclear inclusions. These morphologic approaches have largely been replaced, however, by more specific testing methods, such as direct immunofluorescence techniques or immunoperoxidase staining to detect VZV, HSV, and CMV infection. The diagnosis of acute toxoplasmosis can be made from characteristic histologic changes in lymph nodes or by demonstration of the tachyzoite in biopsy or autopsy specimens of infected tissues.

Detailed descriptions of the changes associated with infections of the placenta are presented in a monograph by Fox [102]. Examination of the placental parenchyma, the membranes, and the cord may provide valuable information for diagnosis of the infection and identification of the mode of transmission to the fetus (in utero or ascending infection).

### Serologic Diagnosis

The serologic diagnosis of infection in the pregnant woman most often requires demonstration of elevated antibody titer against the suspected agent. Ideally, the physician should have available information about the patient's serologic status at the onset of pregnancy to identify women who are unprotected against *T. pallidum*, *T. gondii*, and rubella virus or who are infected with HBV or HIV. Many obstetricians have adopted this valuable practice.

Difficulties in interpreting serologic test results seldom arise when patients are seen shortly after exposure or at the onset of symptoms. In certain infections (e.g., rubella, toxoplasmosis), a relatively rapid increase in antibody levels

may preclude the demonstration, however, of a significant increase in titer in patients who are tested more than 7 days after the onset of the suspected illness. In these circumstances, a diagnosis may be obtained through the measurement of antibodies that increase more slowly over several weeks. Demonstration of IgA and IgE antibodies (in addition to the more conventional use of tests for IgG and IgM antibodies) is useful in the early diagnosis of infection in the pregnant woman, fetus, and newborn, and this should serve as an impetus to commercial firms to make these methods more widely available for health care providers. The same pertains to IgG avidity tests, which have proved accurate in ruling out recently acquired infection with *T. gondii* [103], CMV [104,105], and rubella virus [106,107]. At present, these tests require special techniques and are not performed routinely by most laboratories, so local or state health departments should be consulted for further information regarding their availability.

### Use of Skin Tests

Routine skin tests for diagnosis of tuberculosis should be considered a part of prenatal care. Tuberculin skin tests can be administered to the mother without risk to the fetus.

## Universal Screening

Prenatal care in the United States includes routine screening for serologic evidence of syphilis and rubella infection; culture or antigen evidence of *Chlamydia trachomatis*, group B streptococcus, or HBV infection; screening for urinary tract infection; and skin testing for tuberculosis. Evidence that treatment of the HIV-infected mother significantly reduces virus transmission to the fetus has led to recommendations by the U.S. Public Health Service and others for universal HIV screening for all pregnant women in the United States. Current CDC guidelines support voluntary HIV testing under conditions that simplify consent procedures, while preserving a woman's right to refuse testing [5,108,109].

Pregnant women with known HIV infection should be monitored and given appropriate treatment to enhance mother and fetal well-being and to prevent maternal-to-fetal transmission. Pregnant women should be examined carefully for the presence of HIV-related infections, including gonorrhea, syphilis, and *C. trachomatis*. Baseline antibody titers should be obtained for opportunistic infections, such as *T. gondii*, which are observed commonly in HIV-infected women and which may be transmitted to their fetuses. More detailed information on management of the HIV-infected pregnant woman and her infant is given in Chapter 21.

# DIAGNOSIS OF INFECTION IN THE NEWBORN INFANT

Infants with congenital infection as a result of rubella virus, CMV, HSV, *T. gondii*, or *T. pallidum* may present similarly with one or more of the following abnormalities: purpura, jaundice, hepatosplenomegaly, pneumonitis, and meningoencephalitis. Some findings have specific diagnostic significance (see Tables 1–5 and 1–6).

In certain congenital infections, the organism may be isolated from tissues and body fluids. Infants may excrete CMV and rubella virus in the urine for weeks to months after birth. *T. pallidum* may be found in the CSF, in nasal secretions, and in syphilitic skin lesions. In infants with congenital HIV infection, approximately 30% to 50% are culture-positive or PCR assay–positive at birth, but nearly 100% are positive by 4 to 6 months of life.

Serologic tests are available through state or commercial laboratories for the TORCH group of microorganisms (*T. gondii*, rubella virus, CMV, and HSV) and for certain other congenitally acquired infections. To distinguish passively transferred maternal IgG antibody from antibody produced by the neonate in response to infection in utero, it is necessary to obtain two blood specimens from the infant. Because the half-life of IgG is approximately 3 weeks, the first sample is obtained soon after birth, and the second sample should be obtained at least two half-lives, or approximately 6 weeks, after the first specimen.

IgA, IgE, and IgM antibodies do not cross the placenta. Antigen-specific IgA, IgE, and IgM antibodies in the infant's blood provide evidence of current infection, but few commercial laboratories employ reliable assays for these antibodies for the purpose of identifying congenital infections (as described in a Public Health Advisory from the U.S. Food and Drug Administration outlining the limitations of *Toxoplasma* IgM commercial test kits).

Although most congenital infections occur as a single entity, many HIV-infected mothers are coinfected with other infectious agents that may be transmitted to the newborn. A neonate born to a mother with HIV infection should be considered at risk for other sexually transmitted infections, such as syphilis, gonorrhea, and *C. trachomatis* infection. Coinfection also has been documented for CMV [110,111].

# PREVENTION AND MANAGEMENT OF INFECTION IN THE PREGNANT WOMAN

## Prevention of Infection

The pregnant woman should avoid contact with individuals with communicable diseases, particularly if the pregnant woman is known to be seronegative (e.g., for CMV) or has no prior history of the disease (e.g., with VZV). In some cases, specific measures can be taken. The pregnant woman should avoid intercourse with her sexual partner if he has a vesicular lesion on the penis that may be associated with HSV, or if he is known or suspected to be infected with HIV.

Pregnant women should avoid eating raw or undercooked lamb, pork, and beef because of risk of *T. gondii* contamination. They also should avoid contact with cat feces or objects or materials contaminated with cat feces because these are highly infectious if they harbor oocysts of *T. gondii* (see Chapter 31). Pregnant women should not eat unpasteurized dairy products (including all soft cheeses), prepared meats (hot dogs, deli meat, and paté), and undercooked poultry because these foods often contain *Listeria monocytogenes* (see Chapter 13).

## Immunization

Routine immunization schedules for infants and children with currently available live vaccines, including measles, poliomyelitis, mumps, and rubella, should confer protection against these infections throughout the childbearing years.

Public health authorities and obstetricians generally agree that immunization during pregnancy poses only theoretical risks to the developing fetus. Nevertheless, pregnant women should receive a vaccine only when the vaccine is unlikely to cause harm, the risk for disease exposure is high, and the infection would pose a significant risk to the mother (e.g., influenza) or fetus (e.g., tetanus) [112]. The following are important considerations regarding immunization of the pregnant woman:

- The only vaccines routinely recommended for administration during pregnancy in the United States, when indicated for either primary or booster immunization, are vaccines for tetanus, diphtheria, and influenza [113]. These and other inactivated vaccines, including typhoid fever vaccine, are not considered hazardous to the pregnant woman or her fetus and often provide major benefit when indicated. An example is the use of tetanus toxoid vaccines in areas of the world where unsterile delivery and cord care practices may cause infection and high risk of fatality in the newborn. In the United States, pregnant women are at increased risk for influenza-like illness requiring hospitalization compared with nonpregnant women of similar age. For this reason, routine immunization of pregnant women at the onset of the influenza season is recommended by the Advisory Committee on Infectious Diseases of the CDC [113]. In women at increased risk for certain serious bacterial infections, such as invasive pneumococcal or meningococcal disease (e.g., women with sickle cell disease or HIV infection), immunization should precede pregnancy where possible. If immunization has not occurred before pregnancy, and the risk is significant (e.g., with a meningococcal outbreak in the community), women should be vaccinated.
- Pregnancy is a contraindication to administration of all live vaccines except when susceptibility and exposure are highly probable, and the disease to be prevented constitutes a greater threat to the woman and her fetus than a possible adverse effect of the vaccine. Yellow fever vaccine is indicated for pregnant women who are at substantial risk for imminent exposure to infection (e.g., with international travel). A report of IgM antibodies to yellow fever in the infant of a woman immunized during pregnancy suggests that transplacental transmission of the yellow fever vaccine virus does occur, although the incidence of congenital infection is unknown [114].
- Varicella vaccine should not be administered to pregnant women because the possible effects on fetal development are unknown. When women of childbearing age, including postpubertal girls, are immunized, pregnancy should be avoided for at least 2 months after immunization.
- Because several weeks can elapse before pregnancy is evident, vaccines indicated for any woman of childbearing age should be administered with caution and selectivity. Evidence that prolonged virus shedding occurs after immunization with live virus vaccine suggests that, where possible, pregnancy should be avoided for 2 to 3 months after administration of any live immunizing agent.
- The risk to the mother or fetus from immunization of members of the immediate family or other intimate contacts is uncertain. The use of attenuated measles, rubella, mumps, and varicella vaccines rarely results in transmission of these viruses to susceptible subjects in the immediate environment, but household spread of attenuated polioviruses through contact with recently vaccinated, susceptible individuals in the family is common. From March 1995 through March 2003, 509 pregnant women whose pregnancy outcomes were documented were inadvertently given varicella vaccine (VARIVAX Pregnancy Registry). No offspring had congenital varicella, and the rate of congenital anomalies was no greater than that in the general population. The presence of a pregnant woman in the household is not a contraindication to varicella immunization of a child in that household, and women who are susceptible to varicella should be vaccinated postpartum.

## Use of Immunoglobulin

Human immune serum globulin administered after exposure to rubella, varicella, measles, or hepatitis A virus may modify clinical signs and symptoms of disease, but has not proved to be consistently effective in preventing disease, and presumably viremia, in susceptible individuals. Human immune serum globulin is of undetermined value in protecting the fetus of a susceptible woman against infection with these viruses. Use after maternal exposure to rubella virus should be limited to women to whom therapeutic abortion is unacceptable, in the event of documented infection during pregnancy.

## Antimicrobial Therapy

Almost without exception, antimicrobial agents administered systemically to the mother pass to the fetus. Clinical management of pregnant women with acute infections amenable to therapy should be the same as management of nonpregnant patients, but should include particular attention to the possible effects of the antimicrobial drug on the fetus. Pregnant women with recently acquired acute toxoplasmosis, Lyme disease, and syphilis should undergo treatment as outlined in the specific chapters devoted to those topics. Women who are colonized with *C. trachomatis* or group B streptococci may receive treatment under selected circumstances (discussed in the next section).

A landmark study by Connor and colleagues [115] showed reduction of mother-to-infant transmission of HIV from 25.5% to 8.3% using zidovudine in women who had peripheral $CD4^+$ T lymphocyte counts greater than 200 cells/μL and were mildly symptomatic. The currently recommended treatment regimen in the United States is oral zidovudine administered to pregnant women beginning at 14 to 34 weeks of gestation and continuing

throughout pregnancy, intravenous zidovudine during labor and delivery, and oral zidovudine to the newborn for the first 6 weeks of life (see Chapter 21). This complex and costly regimen is not feasible for resource-limited countries, but studies in Uganda using a single dose of nevirapine administered to the mother during labor and a single dose to the neonate before discharge provided a model for simpler and effective prophylactic therapy [116]. More recent recommendations from the World Health Organization include the use of simple, short course combination prophylactic therapeutic regimens which are effective and prevent development of antiretroviral resistance among infants with breakthrough infections [117].

# INFECTIONS ACQUIRED BY THE NEWBORN INFANT DURING BIRTH

## PATHOGENESIS

The developing fetus is protected from the microbial flora of the maternal genital tract. Initial colonization of the newborn and of the placenta usually occurs after rupture of maternal membranes. If delivery is delayed after membranes rupture, the vaginal microflora can ascend and in some cases produce inflammation of fetal membranes, umbilical cord, and placenta. Fetal infection also can result from aspiration of infected amniotic fluid. Some viruses are present in the genital secretions (HSV, CMV, HBV, or HIV) or blood (HBV, hepatitis C virus, or HIV). If delivery occurs shortly after rupture of the membranes, the infant can be colonized during passage through the birth canal. Various microorganisms may be present in the maternal birth canal, as summarized in Table 1–8, including gram-positive cocci (staphylococci and streptococci); gram-negative cocci (*Neisseria meningitidis* [rarely] and *Neisseria gonorrhoeae*); gram-negative enteric bacilli (*Escherichia coli*, *Proteus* species, *Klebsiella* species, *Pseudomonas* species, *Salmonella*, and *Shigella*); anaerobic bacteria; viruses (CMV, HSV, rubella virus, and HIV); fungi (predominantly *Candida albicans*); *C. trachomatis*; mycoplasmas; and protozoa (*Trichomonas vaginalis* and *T. gondii*). As indicated in Table 1–8, some of these organisms are significantly associated with disease in the newborn infant, whereas others affect the neonate rarely, if at all.

The newborn is initially colonized on the skin; mucosal surfaces including the nasopharynx, oropharynx, conjunctivae, umbilical cord, and external genitalia; and the gastrointestinal tract (from swallowing of infected amniotic fluid or vaginal secretions). In most infants, the organisms proliferate at these sites without causing illness. A few infants become infected by direct extension from the sites of colonization (e.g., otitis media from nasopharyngeal colonization). Alternatively, invasion of the bloodstream can ensue, with subsequent dissemination of infection. The umbilical cord was a particularly common portal of entry for systemic infection before local disinfection methods became routine because the devitalized tissues are an excellent medium for bacterial growth, and because the thrombosed umbilical vessels provide direct access to the bloodstream. Microorganisms also can infect abrasions or skin wounds. At present, the most frequent routes for bloodstream invasion are the lung from aspirated infected amniotic fluid or vaginal contents and the gastrointestinal tract from transmigration of microbial flora across the gut wall.

Infants who develop bacterial sepsis often have specific risk factors not evident in infants who do not develop significant infections. Among these factors are preterm delivery at a gestational age less than 37 weeks, low birth weight, prolonged rupture of maternal membranes, maternal intra-amniotic infection, traumatic delivery, and fetal anoxia. Relative immaturity of the immune system is considered to be one factor increasing risk of infection during the neonatal period. The role of host defenses in neonatal infection is discussed in detail in Chapter 4.

Preterm birth is the most significant risk factor for acquisition of infections in infants immediately before or during delivery or in the nursery. Because of the increasing number of infants with extremely low birth weight and very low birth weight, infection remains a cause of morbidity and mortality. Expansion of treatments for infertility has continued to increase the number of pregnancies with multiple births, and a gestational age of less than 28 weeks is common following these treatments. A summary of 6215 very low birth weight neonates (birth weight 401 to 1500 g) from the National Institute of Child Health and Human Development Neonatal Research Network reported that 21% had one or more episodes of blood culture–positive, late-onset sepsis [119]. Infection rate was inversely correlated with birth weight and gestational age, and infected infants had a significantly prolonged mean hospital stay (79 days) compared with uninfected infants (60 days). Also, infants with late-onset sepsis were significantly more likely to die than uninfected infants (18% versus 7%), especially if they were infected with gram-negative organisms (36%) or fungi (32%) [119].

The value of certain defense mechanisms remains controversial. Vernix caseosa contains antimicrobial proteins (see Chapter 4), and retention of vernix probably provides a protective barrier to the skin. Breast milk influences the composition of the fecal flora by suppression of *E. coli* and other gram-negative enteric bacilli and encouragement of *Lactobacillus* growth. In addition, breast milk contains secretory IgA, lysozymes, white blood cells, and lactoferrin (an iron-binding protein that significantly inhibits the growth of *E. coli* and other microorganisms); however, the role of these constituents in mitigating colonization and systemic infection in the neonate acquired at or shortly after birth is uncertain (see Chapter 5).

The virulence of the invading microorganism is also a factor in the pathogenesis of neonatal sepsis. Certain phage types of *S. aureus* (types 80 and 81) were responsible for most cases of disease in the staphylococcal pandemic of the 1950s. Phage group 2 *S. aureus* strains have been responsible for staphylococcal scalded skin syndrome sometimes seen in neonates (toxic epidermal necrolysis). Other evidence suggests that the K1 capsular antigens of *E. coli* and type III strains of group B streptococcus possess virulence properties that enhance their propensity for invasion of the blood-brain barrier during bacteremia compared with non-K1 and non–type III strains.

## MICROBIOLOGY

The agents responsible for early-onset (before 7 days) neonatal sepsis are found in the maternal birth canal [120,121]. Most of these organisms are considered to be saprophytic, but occasionally can be responsible for maternal infection and its sequelae, including endometritis and puerperal fever. The microbial flora of the adult female genital tract and their association with neonatal infection and disease are reviewed in Table 1–9.

Before the introduction of the sulfonamides and penicillin in the 1940s, gram-positive cocci, particularly group A streptococci, were responsible for most cases of neonatal sepsis. After the introduction of antimicrobial agents, gram-negative enterics, in particular *E. coli*, were the predominant causes of serious bacterial infections of the newborn. An increase in serious neonatal infection caused by group B streptococci was noted in the early 1970s, and group B streptococci and *E. coli* continue to be the most frequent causative agents for early-onset neonatal sepsis and late-onset sepsis in term infants. By contrast, late-onset (after 7 days) sepsis in preterm neonates remaining in the neonatal intensive care unit for weeks or months is typically caused by commensal organisms (e.g., coagulase-negative staphylococci and *Enterococcus*) and organisms acquired from the mother and from the nursery environment.

The bacteria responsible for neonatal sepsis are discussed in Chapter 6. Mycoplasmas, anaerobic bacteria, and viruses (including HSV, HBV, CMV, and HIV) that colonize the maternal genital tract also are acquired during birth.

## DIAGNOSIS

Review of the maternal record provides important clues for diagnosis of infection in the neonate. Signs of illness during pregnancy; exposure to sexual partners with transmissible infections; and results of cultures (e.g., for *C. trachomatis*, *N. gonorrhoeae*, or group B streptococci), serologic tests (e.g., for HIV infection, rubella, HBV, hepatitis C virus, or syphilis), and tuberculin skin tests or chest radiographs should be identified in the pregnancy record. The delivery chart should be checked for peripartum events that indicate risk of sepsis in the neonate, including premature rupture of membranes; prolonged duration (>18 hours) of rupture of membranes; evidence of fetal distress and fever; or other signs of maternal infection such as bloody diarrhea, respiratory or gastrointestinal signs (i.e., enterovirus), indications of large concentrations of pathogens in the genitalia (as reflected in bacteriuria caused by group B streptococci), and evidence of invasive bacterial infections in prior pregnancies.

**TABLE 1–9** Association of Neonatal Disease with Microorganisms Present in the Maternal Birth Canal

| Organism | Significant | Uncommon | Rare |
|---|---|---|---|
| Bacteria | Group A streptococci | *Staphylococcus aureus* | *Lactobacillus* |
| | Group B streptococci | α-hemolytic streptococci | *Staphylococcus epidermidis* |

*CMV, cytomegalovirus; HBV, hepatitis B virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; HSV, herpes simplex virus; LCV, lymphocytic choriomeningitis virus.*

The clinical diagnosis of systemic infection in the newborn can be difficult because the initial signs of infection may be subtle and nonspecific. Not only are the signs of infectious and noninfectious processes similar, but also the signs of in utero infection are indistinguishable from signs of infections acquired during the birth process or during the first few days of life. Respiratory distress, lethargy, irritability, poor feeding, jaundice, emesis, and diarrhea are associated with various infectious and noninfectious causes.

Some clinical manifestations of neonatal sepsis, such as hepatomegaly, jaundice, pneumonitis, purpura, and meningitis, are common to many infections acquired in utero or during delivery. Certain signs are related to specific infections (see Tables 1–6 and 1–7). Many signs of congenital infection are not evident at birth. HBV infection should be considered in an infant with onset of jaundice and hepatosplenomegaly between 1 and 6 months of age; CMV infection acquired at or soon after delivery is associated with an afebrile protracted pneumonitis; enterovirus infection should be considered in an infant with CSF pleocytosis in the first months of life. Most infants with congenital HIV infection do not have signs of disease during the first months of life. Uncommonly, signs may be present at birth. Srugo and colleagues [122] described an infant with signs of meningoencephalitis at 6 hours of life; HIV was subsequently isolated from CSF.

Most early-onset bacterial infections are nonfocal except in the circumstance of respiratory distress at or shortly after birth, in which the chest radiograph reveals pneumonia. Focal infections are frequent with late-onset neonatal sepsis and include otitis media, pneumonia, soft tissue infections, urinary tract infections, septic arthritis, osteomyelitis, and peritonitis. Bacterial meningitis is of particular concern because of the substantial mortality rate and the significant morbidity in survivors. Few infants have overt meningeal signs, and a high index of suspicion and examination of the CSF are required for early diagnosis.

Available routine laboratory methods provide limited assistance in the diagnosis of systemic infections in the newborn infant. In bacterial sepsis, measurement of the total white blood cell count can be variable and supports a diagnosis of bacterial sepsis only if it is high (>30,000 cells/$mm^3$) or very low (<5000 cells/$mm^3$). Immunoglobulin is produced by the fetus and newborn infant in response to infection, and increased levels of IgM have been measured in the serum of newborns with infections (i.e., syphilis, rubella, cytomegalic inclusion disease, toxoplasmosis, and malaria) acquired transplacentally. Increased levels of IgM also result from postnatally acquired bacterial infections. Not all infected infants have increased levels of serum IgM, however, and some infants who do have elevated concentrations of total IgM are apparently uninfected. Identification of increased levels of total IgM in the newborn suggests an infectious process acquired before or shortly after birth, but this finding is not specific and is of limited assistance in diagnosis and management.

Because inflammation of the placenta and umbilical cord may accompany peripartum sepsis, pathologic examination of sections of these tissues may assist in the diagnosis of infection in the newborn. Histologic evidence of inflammation also is noted in the absence of evidence of neonatal sepsis, however. In the immediate postnatal period, gastric aspirate, pharyngeal mucus, or fluid from the external ear canal has been used to delineate exposure to potential pathogens, but is not useful in the diagnosis of neonatal sepsis.

Isolation of microorganisms from a usually sterile site, such as blood, CSF, or skin vesicle fluid, or from a suppurative lesion or a sterilely obtained sample of urine remains the only valid method of diagnosing systemic infection. Aspiration of any focus of infection in a critically ill infant (e.g., needle aspiration of middle ear fluid in an infant with otitis media or from the joint or metaphysis of an infant with osteoarthritis) should be performed to determine the etiologic agent. In infants with very low birth weight, commensal microorganisms, such as coagulase-negative staphylococci, *Enterococcus*, or *Candida*, isolated from a usually sterile body site should be considered pathogens until proven otherwise. Culture of infectious agents from the nose, throat, skin, umbilicus, or stool indicates colonization; these agents may include the pathogens that are responsible for the disease, but in themselves do not establish the presence of active systemic infection.

PCR assay is useful to detect the nucleic acid of various important pathogens including viruses and *Pneumocystis jiroveci*. When appropriate, serologic studies should be performed to ascertain the presence of in utero or postnatal infection. Serologic tests for HIV, rubella, parvovirus B19, *T. gondii*, and *T. pallidum* are available through local or state laboratories. For some of these infections (e.g., rubella), the serologic assay measures IgG. To distinguish passively transferred maternal antibody from antibody derived from infection in the neonate, it is necessary to obtain two blood specimens from the infant. Because the half-life of IgG is estimated to be 23 days, the first sample is obtained soon after birth, and the second sample should be obtained at least two half-lives, or approximately 6 weeks, after the first specimen. Measurement of IgM antibody provides evidence of current infection in the neonate, but none of these assays has proven reliability at present.

## MANAGEMENT

Successful management of neonatal bacterial sepsis depends on a high index of suspicion based on maternal history and infant signs, prompt initiation of appropriate antimicrobial therapy while diagnostic tests are performed, and meticulous supportive measures. If the physician suspects bacterial infection in a newborn, culture specimens should be obtained, and treatment with appropriate antimicrobial agents should be initiated immediately. Generally, initial therapy must provide coverage against gram-positive cocci, particularly group B and other streptococci, and gram-negative enteric bacilli. Ampicillin is the preferred agent with effectiveness against gram-positive cocci and *L. monocytogenes*. The choice of therapy for gram-negative infections depends on the current pattern of antimicrobial susceptibility in the local community. Most experts prefer ampicillin and gentamicin therapy for early-onset presumptive sepsis, with the addition of cefotaxime for presumptive bacterial meningitis [123]. Intrapartum antimicrobial therapy can yield

drug concentrations in the blood of the newborn infant sufficient to suppress growth of group B streptococci and possibly other susceptible organisms in blood obtained for culture. The requirement for more than one blood specimen for the microbiologic diagnosis of early-onset sepsis places a substantial burden on the clinician.

An algorithm has been devised to guide empirical management of neonates born to mothers who received intrapartum antimicrobial prophylaxis for prevention of early-onset group B streptococcal infection [124]. These infants may be divided into three management groups:

1. Neonates who have signs of sepsis or neonates whose mothers are colonized with group B streptococci and have chorioamnionitis should receive a full diagnostic evaluation with institution of presumptive treatment.
2. Term neonates who appear healthy and whose mothers received penicillin, ampicillin, or cefazolin 4 or more hours before delivery do not require further evaluation or treatment.
3. Healthy-appearing term neonates whose mothers received prophylaxis less than 4 hours before delivery and neonates born at less than 35 weeks of gestation whose mothers received prophylaxis of any duration before delivery should be observed for 48 hours or longer and should receive a limited evaluation, including white blood cell count and differential and blood culture [124].

Infants in the first two categories are readily identified, but assignment of infants to the third category is often problematic because of the vague end points. Recommendations for prevention and treatment of early-onset group B streptococcal infection are discussed in Chapter 12.

The choice of antibacterial drugs should be reviewed when results of cultures and susceptibility tests become available. The clinician should take care to select drugs that have been studied for appropriate dose, interval of dosing, and safety in neonates, especially very low birth weight infants, and that have the narrowest antimicrobial spectrum that would be effective (see Chapter 37). The duration of therapy depends on the initial response to the appropriate antibiotics—typically 10 days in most infants with sepsis, pneumonia, or minimal or absent focal infection; a minimum of 14 days for uncomplicated meningitis caused by group B streptococci or *L. monocytogenes*; and 21 days for gram-negative enteric bacilli [124]. The clinical pharmacology of antibiotics administered to the newborn infant is unique and cannot be extrapolated from adult data on absorption, excretion, and toxicity. The safety of new antimicrobial agents is a particular concern because toxic effects may not be detected until several years later (see Chapter 37).

Development of antimicrobial drug resistance in microbial pathogens is a constant concern. Group B streptococci remain uniformly susceptible to penicillins and cephalosporins, but many isolates now are resistant to erythromycin and clindamycin [125]. Administration of one or two doses of a penicillin or cephalosporin as part of a peripartum prophylactic regimen for prevention of group B streptococcal infection in the neonate should not significantly affect the genital flora, but monitoring should be continued to detect alterations in flora and antibiotic susceptibility. Because the nursery is a small, closed community, development of resistance is a greater concern with nosocomial infections than with infections acquired in utero or at delivery.

Despite the use of appropriate antimicrobial agents and optimal supportive therapy, mortality from neonatal sepsis remains substantial. To improve survival and decrease the severity of sequelae in survivors, investigators have turned their attention to studies of adjunctive modes of treatment that supplement the demonstrated deficits in the host defenses of the infected neonate. These therapies include use of standard hyperimmune immunoglobulins, leukocyte growth factors, and pathogen-specific monoclonal antibody preparations.

Antiviral therapies are available for newborns infected with HSV (acyclovir), VZV (acyclovir), and HIV. Acyclovir and zidovudine for HIV are well tolerated in pregnant women. Because early use of acyclovir for herpes simplex infections in neonates has been associated with improved outcome, physicians may choose to begin therapy for presumptive HSV disease and reevaluate when information on clinical course and results of cultures and PCR assay become available.

A phase II trial examining safety, pharmacodynamics, and efficacy of ganciclovir treatment for symptomatic congenital CMV infection established the safe dose in infants and showed an antiviral effect with suppression of viruria [126,127]. Neutropenia (63%), thrombocytopenia, and altered hepatic enzymes were noted in most of the infants, with nearly half of the infants requiring dosage adjustments because of severe neutropenia. A phase III randomized, controlled trial of intravenous ganciclovir for 6 weeks in 100 CMV-infected infants with central nervous system involvement at birth maintained hearing or showed hearing improvement in 84% of infants who received ganciclovir compared with 41% of control infants (see Chapter 23).

# PREVENTION

## Immunoprophylaxis

Passive immunoprophylaxis with specific hyperimmune immunoglobulin or monoclonal antibody preparations is indicated for the prevention of hepatitis B, varicella and respiratory syncytial virus infection in infants at risk for these infections. Details are provided in Chapter 38.

Universal immunization of infants with hepatitis B vaccine has been recommended by the American Academy of Pediatrics since 1992 [128]. Prior strategies of selective vaccination in high-risk populations and serologic screening of all pregnant women for HBsAg had little impact on control of HBV infections or their sequelae, and public health authorities believe that infant immunization offers the most feasible approach to universal protection and eventual eradication of the disease. Infants born to HBsAg-positive women should be immunized at birth and receive hepatitis B immunoglobulin at or shortly after birth. This prevention strategy may be improved if a birth dose of hepatitis B vaccine is universally recommended, providing additional coverage for infants whose maternal records are incorrect or unavailable before hospital discharge.

### Chemoprophylaxis

After administration to the mother, antimicrobial agents capable of crossing biologic membranes can achieve pharmacologic concentrations in the fetus comparable with concentrations in well-vascularized maternal tissues. Prevention of group B streptococcal infection in the newborn by administration of ampicillin to the mother was shown by Boyer and colleagues [129] and other investigators in 1983 (see Chapter 12). A prevention strategy initially recommended by the American Academy of Pediatrics in 1992[130] was revised in 1997, and current recommendations from the CDC are endorsed by the American Academy of Pediatrics, the American College of Obstetricians and Gynecologists, and the American Academy of Family Physicians. These organizations recommend universal culture screening of all pregnant women at 35 to 37 weeks of gestation and administration of intravenous penicillin during labor [3].

Fetal drug concentrations can exceed 30% of the maternal blood concentrations [131], and concentrations bactericidal against group B streptococci can be achieved in amniotic fluid 3 hours after a maternal dose (see Chapters 12 and 37). Parenteral antimicrobial therapy administered to the mother in labor essentially treats the fetus earlier in the course of the intrapartum infection. If the fetus has been infected, the regimen is treatment, not prophylaxis, and for some infected fetuses the treatment administered in utero is insufficient to prevent early-onset group B streptococcal disease [132]. Although the prophylactic regimen has decreased the incidence of early-onset group B streptococcal disease (by >80% in a Pittsburgh survey [133], the regimen has had no impact on the incidence of late-onset disease [3].

Other modes of chemoprophylaxis administered to the neonate include ophthalmic drops or ointments for prevention of gonococcal ophthalmia and zidovudine to infants born to HIV-infected mothers. Administration of antibacterial agents to infants with minimal or ambiguous clinical signs is considered therapy for presumed sepsis and should not be considered prophylaxis.

# INFECTIONS OF THE NEWBORN INFANT IN THE FIRST MONTH OF LIFE

When fever or other signs of systemic infection occur in the first weeks or months of life, various sources of infection should be considered: (1) congenital infections with onset in utero; (2) infections acquired during the birth process from the maternal genital tract; (3) infections acquired in the nursery; (4) infections acquired in the household after discharge from the nursery; and (5) infection that suggests an anatomic defect, underlying immunologic disease, or metabolic abnormality.

## PATHOGENESIS AND MICROBIOLOGY

### Congenital Infections

Signs of congenital infection may not appear for weeks, months, or years after birth. Diagnosis and management are discussed in the disease chapters.

### Infections Acquired during Delivery

Although maternal intrapartum prophylaxis has reduced the incidence of early-onset group B streptococcal disease, it has not altered the incidence of late-onset disease [3,133], with signs occurring from 6 to 89 days of life, up to 6 months of age in infants with very low birth weight. The pathogenesis of late-onset group B streptococcal disease remains obscure, but it is likely that even when vertical transmission from the mother at birth is prevented, exposure to either the mother (in whom colonization resumes after delivery) or other colonized family members and caregivers can serve as a source for colonization through direct contact. It is unknown why sepsis develops without warning in an infant who has no risk factors for sepsis and was well for days to weeks; this concern also is relevant in infants who acquire late-onset disease as a result of *E. coli* and *L. monocytogenes*.

### Nursery-Acquired Infections

After arrival in the nursery, the newborn may become infected by various pathways involving either human carriers or contaminated materials and equipment. Human sources in the hospital include personnel, mothers, and other infants. The methods of transmission may include the following:

- Respiratory droplet spread from adults or other newborn infants. Outbreaks of respiratory virus infections, including influenza, respiratory syncytial, and parainfluenza viruses, in prolonged-stay nurseries are frequent [132]. Methods for identification and control are provided in Chapter 35.
- Carriage of the microorganism on the hands of hospital personnel. A study has suggested that the hands may be not only a means of transmission, but also a significant reservoir of bacteria [134].
- Suppurative lesions. Although spread of staphylococcal and streptococcal infections to infants or mothers may be associated with asymptomatic carriers, the most serious outbreaks have been caused by a member of the medical or nursing staff with a significant lesion.
- Human milk. CMV, HIV, HSV, human T-cell lymphotropic virus type I [135], human T-cell lymphotropic virus type II [136], and HBsAg have been identified in mother's milk and may be transmitted to the neonate by this route. CMV-infected milk from banks can be dangerous for infants lacking passively transferred maternal antibody.

Breast milk transmission of HIV is of concern because of the importance of breast-feeding in providing nutrition and immunologic protection in the first year of life. Breast milk has been documented as the likely source of HIV infection in neonates whose mothers were transfused with HIV-infected blood after delivery or in whom disease developed postpartum through sexual contact [137]. These acute infections must be differentiated from the usual event, in which the mother is infected throughout pregnancy. Infection during the acute period occurs before development of antibody and may be a time when breast milk has a high titer of transmissible virus.

Because of the importance of breast-feeding for infant nutrition in developing countries, the World Health

Organization initially recommended that women in developing countries be encouraged to breast-feed despite HIV status [138]. By contrast, in the United States and Western Europe, HIV-infected mothers were discouraged from breast-feeding because other forms of nutrition were available [139]. In July 1998, the United Nations revised its position and issued recommendations to discourage HIV-infected women from breast-feeding, recognizing that many infants were infected by the breast milk of HIV-infected mothers. The recommendation also noted that in some regions and cultures, women are stigmatized for not breast-feeding, and alternatives such as formula are unaffordable or unsafe. The number of antenatal women in developing countries that lack resources for prevention in pregnancy has reached alarming proportions: 70% of women at a prenatal clinic in Zimbabwe and 30% of women in urban areas in six African countries were infected. The United Nations survey indicated that by 2000, breast-feeding would be responsible for more than one third (>200,000) of children newly infected with HIV unless some attempts were made to limit this route of transmission [140]. Current efforts to prevent breast-feeding transmission include improved dissemination of prophylactic regimens for pregnant women and their newborns [117]. However, availability of such regimens appears to be limited to ~45% of HIV infected pregnant women in low and middle income countries [118].

Infection of breast milk by bacterial pathogens such as *S. aureus*, group B streptococci, *L. monocytogenes* [141], and *Salmonella* species can result in neonatal disease. Bacteria that are components of skin flora, including *Staphylococcus epidermidis* and α-hemolytic streptococci, are frequently cultured from freshly expressed human milk and are unlikely to be associated with disease in the breast-fed infant. If these bacteria are allowed to multiply in banked breast milk, infection of the neonate is theoretically possible, but no substantive data have supported this possibility.

Other possible sources of infection in the nursery include the following:

- Blood used for replacement or exchange transfusion in neonates should be screened for safety using validated, efficacious methods, including tests for hepatitis B antigen, hepatitis C, HIV antibody, CMV antibody, and *Plasmodium* species in malaria-endemic areas.
- Equipment has been implicated in common-source nursery outbreaks, usually including contaminated solutions used in nebulization equipment, room humidifiers, and bathing solutions. Several gram-negative bacteria, including *Pseudomonas aeruginosa*, *Serratia marcescens*, and *Flavobacterium*, have been termed "water bugs" because of their ability to multiply in aqueous environments at room temperature. In recent years, few solution-related or equipment-related outbreaks caused by these organisms have been reported because of the scrupulous infection control practices enforced in most intensive care nurseries.
- Catheterization of the umbilical vein and artery has been associated with sepsis, umbilical cellulitis, and abscess formation, but careful hygienic practices with insertion of these devices make these complications rare. Intravenous alimentation using central venous catheters has been lifesaving for some infants, but also is associated with increased risk for catheter-related bacteremia or fungemia.
- Parenteral feeding with lipid emulsions has been associated with neonatal sepsis caused by coagulase-negative staphylococci and *Candida* species. Strains of staphylococci isolated from infected ventricular shunts or intravascular catheters produce a slime or glycocalyx that promotes adherence and growth of colonies on the surfaces and in the walls of catheters manufactured with synthetic polymers. The slime layer also protects the bacteria against antibiotics and phagocytosis. The introduction of lipid emulsion through the venous catheter provides nutrients for growth of the bacteria and fungi [142].

Hand hygiene remains the most important element in controlling the spread of infectious diseases in the nursery (see Chapter 35). Hand hygiene measures should be implemented before and after every patient contact. Surveys of hospital employees indicate that rigorous adherence to hand hygiene, although the most simple of infection control techniques, is still lacking in most institutions. A study by Brown and colleagues [143] in a Denver neonatal intensive care unit indicated that compliance with appropriate hand-washing techniques was low for medical and nursing personnel. Compliance was monitored using a direct observation technique; of 252 observed encounters of nurses, physicians, and respiratory therapists with infants, 25% of the personnel broke contact with the infant by touching self (69%) or touching another infant (4%), and 25% did not wash before patient contact.

Waterless, alcohol-based hand hygiene products are routinely used in nurseries, with surveys indicating their rapid acceptance by nursery personnel including physicians. Their ease of application and time saved through reduction in the need for hand washing should increase adherence with hand hygiene recommendations.

Early patient discharge at 24 or 48 hours was common several years ago as hospitals and third-party payers have attempted to reduce costs of health care. A cohort study of more than 300,000 births in Washington documented that newborns discharged home early (before 30 hours after birth) were at increased risk for rehospitalization during the first month of life; the leading causes were jaundice, dehydration, and sepsis, with onset within 7 days after discharge. Among 1253 infants who were rehospitalized within the first month of life, sepsis was the cause in 55 infants (4.4%) who were discharged early, in contrast to 42 infants (3.4%) who were discharged late [144]. These and other reports, combined with corrective legislation in many states, have led to recommendations that newborns remain hospitalized at least 48 hours after vaginal birth and 72 hours after cesarean section delivery.

## Community-Acquired Infections

The newborn infant is susceptible to many of the infectious agents that colonize other members of the household and caregivers. The physician should consider illnesses in these contacts before discharging an infant from the hospital. If signs of an infectious disease develop

after 15 to 30 days of life in an infant who was healthy at discharge and had no significant risk factors during gestation or delivery, the infection was probably acquired from a household or community contact. Suppurative lesions related to *S. aureus* in a household member can expose an infant to a virulent strain that causes disseminated infection. A careful history of illness in family members can suggest the source of the infant's disease (e.g., respiratory viruses, skin infections, a prolonged illness with coughing).

An infant also can be a source of infection for household contacts. An infant with congenital rubella syndrome can shed virus for many months and is a significant source of infection for susceptible close contacts. The same is true for an infant with vesicular lesions of herpes simplex or a syphilitic infant with rhinitis or skin rash.

## Infections That Indicate Underlying Abnormalities

Infection may serve as a first clue indicating an underlying anatomic, metabolic, or immune system abnormality. Infants with galactosemia, iron overload, chronic granulomatous disease, and leukocyte adhesion defects are susceptible to certain invasive gram-negative infections. Genitourinary infection in the first months of life can suggest an anatomic or a physiologic defect of the urinary tract. Similarly, otitis media in the first month of life may be an indication of a midline defect of the palate or a eustachian tube dysfunction. Meningitis caused by non-neonatal pathogens (e.g., coagulase-negative staphylococci) can be a clue to the presence of a dermoid sinus tract to the intradural space. In infants with underlying humoral immune defects, systemic infections may not develop until passively acquired maternal antibody has dissipated. Because the half-life of IgG is about 3 weeks, such infections are likely to occur after 3 months of age.

CHAPTER 2

# Neonatal Infections: A Global Perspective

Gary L. Darmstadt ✪ Anita K. M. Zaidi ✪ Barbara J. Stoll

CHAPTER OUTLINE

One of the greatest challenges in global public health is to eliminate the gaps between high-income and low-income countries in health care resources, access to preventive and curative services, and health status outcomes. Although child and infant mortality burden has declined substantially in recent decades [1,2], neonatal mortality, especially deaths in the first week of life, has changed relatively little [3]. Worldwide, an estimated 3.8 million neonatal deaths occur annually, accounting for 41% of deaths in children younger than age 5 years [4]. Of these deaths, 99% occur in low-income and middle-income countries [3], in the context of poverty, high-risk newborn care practices, poor care seeking and access to quality care, and poorly functioning health systems. Causes of neonatal mortality, especially in low-income countries, are difficult to ascertain, partly because many of these deaths occur at home, unattended by medical personnel, in settings without vital registration systems, and partly because critically ill neonates often present with nondiagnostic signs and symptoms of disease.

Serious infections, intrapartum-related neonatal deaths (i.e., "birth asphyxia") [5], and complications of prematurity are the major direct causes of neonatal death worldwide [3]. Malnutrition and low birth weight (LBW) underlie most of these deaths [6]. Globally, serious neonatal infections cause an estimated 36% of neonatal deaths [3]. In settings with very high mortality (neonatal mortality rate >45 per 1000 live births), neonatal infections are estimated to cause 40% to 50% of all neonatal deaths [3,7]. Neonatal mortality related to infection could be substantially reduced by simple, known preventive interventions before and during pregnancy, labor, and delivery, and by preventive and curative interventions in the immediate postnatal period and in the early days of life [8–12]. This chapter reviews the global burden of infectious diseases in the newborn, direct and indirect causes of neonatal mortality attributed to infection, specific infections of relevance in low-income and middle-income countries, and strategies to reduce the incidence of neonatal infection and morbidity and mortality in infants who do become infected.

## GLOBAL BURDEN OF NEONATAL INFECTIONS

### INFECTION AS A CAUSE OF NEONATAL DEATH

Most infectious-related neonatal deaths are due to bacterial sepsis and meningitis, respiratory infection, neonatal tetanus, diarrhea, and omphalitis. Neonatal deaths caused by infection may occur early in the neonatal period, in the first 7 days of life, and are usually attributable to infection acquired during the peripartum process. Late neonatal deaths, occurring from 8 to 28 days of life, are most commonly due to acquisition of pathogens from the environment in which the vulnerable newborn is placed.

In low-income and middle-income countries, because most births and neonatal deaths occur at home and are not attended by medical personnel, deaths are underreported,

DOI: 10.1016/B978-1-4160-6400-8.00002-X

and information on cause of death is often incomplete. Very few published studies worldwide present detailed surveillance data on numbers of births and neonatal deaths and on probable causes of death. Although hospital-based studies are important for accurately determining causes of morbidity and mortality, they may not reflect what is happening in the community, and because of selection bias, they may not be representative of the population. One review summarized 32 community-based studies that were published during 1990-2007 [13]. Infection-specific mortality was found to range from 2.7 per 1000 live births in South Africa to 38.6 per 1000 live births in Somalia. Overall, 8% to 80% (median 36.5%, interquartile range 26% to 49%) of all neonatal deaths in developing countries were found to be attributable to infections [13]. Significant data gaps exist, however, especially from countries with low resources. There is a need for carefully conducted population-based studies that assess the number and causes of neonatal deaths in low-income and middle-income countries.

In the absence of better data, global estimates for causes of neonatal deaths have been derived through statistical modeling, extrapolating from evidence available from several countries at different levels of development and neonatal mortality rates [14]. According to these estimates, infections are the largest cause of neonatal mortality, accounting for 36% of all neonatal deaths; sepsis, pneumonia, and meningitis together account for 26% of neonatal deaths, whereas tetanus and diarrhea account for 7% and 3% [3]. This translates to 1.4 million neonatal deaths from infections, most of which can be averted with appropriate prevention and management [8,15].

## INCIDENCE OF NEONATAL SEPSIS, BACTEREMIA, AND MENINGITIS AND ASSOCIATED MORTALITY

Hospital and community-based studies from low-income and middle-income countries were reviewed to determine the incidence of neonatal sepsis, bacteremia, and meningitis; the case-fatality rates (CFRs) associated with these infections; and the spectrum of bacterial pathogens in different regions of the world. Cases reported occurred among infants born in hospitals or homes, and infants referred from home or other health facilities. Investigators reviewed 77 studies from low-income and middle-income countries [16–91] published during 1980-2009 to evaluate neonatal sepsis and meningitis in different geographic regions. Of these studies, 62 were primarily reports of neonatal sepsis, and 18 presented data on bacterial meningitis. Most studies did not distinguish among maternally acquired, community-acquired, and nosocomial infections. Table 2–1 summarizes data by region.

In all regions, clinically suspected sepsis was responsible for a substantial burden of disease, with high CFRs reported in most studies. Overall, incidence of clinical neonatal sepsis ranged from 2 to 29.8 per 1000 live births. A carefully conducted population-based surveillance study from Mirzapur, a rural part of Bangladesh, attempted to capture all births and all cases of sepsis in a well-defined population through active, household-level surveillance [41]. The incidence of clinically suspected neonatal infection was approximately 50 per 1000 live births [41]. Reported CFRs for neonatal sepsis in the above-mentioned reviewed studies [16–91] ranged from 1% to 69%. Only six studies reported CFRs less than 10%, whereas most of the studies reported sepsis-associated CFRs greater than 30%.

Information on incidence rates of neonatal bacteremia (sepsis confirmed by isolation of bacteria from the blood) from developing countries is extremely limited. Berkley and associates [30] reported a bacteremia rate of 5.5 per 1000 live births in rural Kenya, which is most likely an underestimate because only infants presenting to their referral hospital from the surrounding catchment area were included, and no active case-finding through community surveillance was conducted. In Mirzapur, Bangladesh, active population-based, household-level newborn illness surveillance detected an incidence rate of bacteremia of 3 per 1000 person-neonatal periods [41], a rate that is comparable with incidence of early-onset neonatal sepsis reported in the United States and incidence of neonatal sepsis reported in Israel [51,92,93].

Fewer studies on neonatal meningitis were available to evaluate incidence and CFRs by region. The incidence of neonatal meningitis ranged from 0.33 to 7.3 per 1000 live births (average 1 per 1000 live births), with CFRs ranging from 13% to 59%.

Using these hospital and community-based rates and estimates from the United Nations of approximately 122,266,000 births per year in the low-income and middle-income countries of the world [94], we estimate that 245,000 to 3,668,000 cases of neonatal sepsis and 40,000 to 900,000 cases of neonatal meningitis occur in developing countries each year. The range is large because of the imprecision of available data.

**TABLE 2–1** Incidence and Case-Fatality Rate (CFR) for Sepsis and Meningitis from Hospital and Community-Based Studies in Low-Income and Middle-Income Countries

| Region | Incidence of Sepsis (Cases per 1000 Live Births) | CFR (%) | Incidence of Meningitis (Cases per 1000 Live Births) | CFR (%) |
|---|---|---|---|---|
| India/Pakistan/Southeast Asia/Pacific | 2.4-29.8 | 2-69 | 0.63-7.3 | 45 |
| Sub-Saharan Africa | 6-22.9 | 27-56 | 0.7-1.9 | 18-59 |
| Middle East/North Africa | 1.8-12 | 13-45 | 0.33-1.5 | 16-32 |

## BACTERIAL PATHOGENS ASSOCIATED WITH INFECTIONS IN DIFFERENT GEOGRAPHIC REGIONS

Historical reviews from developed countries have shown that the predominant organisms responsible for neonatal infections change over time [95,96]. Prospective microbiologic surveillance is important to guide empirical therapy and to identify potential targets for vaccine development, to identify new agents of importance for neonates, to recognize epidemics, and to monitor changes over time. The organisms associated with neonatal infection are different in different geographic areas, reinforcing the need for local microbiologic surveillance. In areas where blood cultures in sick neonates cannot be performed, knowledge of the bacterial flora of the maternal genital tract may serve as a surrogate marker for organisms causing early-onset neonatal sepsis, meningitis, and pneumonia. Most studies on the causes of neonatal sepsis and meningitis are hospital reviews that include data on infants born in hospitals and infants transferred from home or other facilities.

A more recent review highlighted the scarcity of data on pathogens associated with neonatal sepsis and meningitis in low-income and middle-income countries [97]. This review found 63 studies published during 1980-2007 that reported etiologic data from low-income and middle-income countries [97]. The review also included findings from the Young Infant Clinical Signs Studies and community-based data from Karachi. Only 12 of these studies focused on community-acquired infections. In most of the remaining studies, it was difficult to determine whether infections were of maternal origin or were hospital-acquired or community-acquired. Because of insufficient information provided, assumptions of community-acquired infections were made if this was implied by the study setting. The possible inclusion of some nosocomial infections cannot be ruled out. Also, the infants' ages at the time of infection were not always specified. The studies varied in the detail with which culture methods were presented.

Table 2–2 gives further details about the distribution of organisms by geographic region. The review found 19 studies that reported etiologic data for the entire neonatal period. In the aggregated data of these studies, the ratio of gram-negative to gram-positive organisms was 1.6:1, and *Staphylococcus aureus*, *Escherichia coli*, and *Klebsiella* species collectively caused almost half of all infections. This pattern was consistent across all regions except Africa, where gram-positive organisms were predominant owing to higher frequency of *S. aureus*, *Streptococcus pneumoniae*, and *Streptococcus pyogenes*.

The etiology of early-onset neonatal sepsis in low-income and middle-income countries was presented in 44 facility-based studies. One fourth of all episodes of

*Adapted from Zaidi AK, et al. Pediatr Infect Dis J 28(1 Suppl):S10-S18, 2009.*

early-onset neonatal sepsis were caused by *Klebsiella* species, 15% were caused by *E. coli*, 18% were caused by *S. aureus*, 7% were caused by group B streptococci (GBS), and 12% were caused collectively by *Acinetobacter* species and *Pseudomonas* species The overall ratio of gram-negative organisms to gram-positive organisms was 2:1. In African countries, the ratio of gram-positive organisms to gram-negative organisms was equal, however, with a larger proportion of infections caused by *S. aureus* and GBS. *Pseudomonas* species and *Acinetobacter* species were found to be more common in East Asia, Pacific, and South Asian countries. *S. aureus* was uncommon in East Asia and Latin America compared with other regions.

The review also found 11 studies that reported etiologic data on community-acquired infections occurring between 7 and 59 days of life. Almost half of the isolates in this age group were from the large World Health Organization (WHO)–sponsored multicenter Young Infant Study conducted in the early 1990s in four developing countries: Ethiopia, The Gambia, Papua New Guinea, and the Philippines [71,98–104]. The ratio of gram-negative to gram-positive organisms in this group was 0.8:1, with higher proportions of *Salmonella* species, *Haemophilus influenzae*, *S. pneumoniae*, and *S. pyogenes* compared with the first week of life [97].

Although data are limited, studies involving home-delivered infants or infants from maternity hospitals and rural referral hospitals found gram-negative organisms to be more than three times as common as gram-positive organisms (ratio of 3:1 among home births, 3.5:1 among rural referral hospitals) [97]. Three gram-negative bacteria (*E. coli*, *Klebsiella* species, and *Pseudomonas* species) accounted for 43% to 64% of all infections, and gram-positive *S. aureus* accounted for 8% to 21% of all infections. Among infants born at home, gram-negative organisms were responsible for 77% of all neonatal infections. In Mirzapur, Bangladesh, among home-born newborns identified through population-based household surveillance, half of all culture-proven episodes of suspected sepsis were due to gram-negative organisms, including *Klebsiella* species, *Pseudomonas* species, *Acinetobacter* species, and *Enterobacter* species. Among gram-positive cultures, *S. aureus* was the most common isolate, responsible for one third of all positive cultures [41].

## INCIDENCE OF GROUP B STREPTOCOCCAL COLONIZATION AND INFECTION

The spectrum of organisms presented in this review differs from what is known from developed countries. Although GBS remains the most important bacterial pathogen associated with early-onset neonatal sepsis and meningitis in many developed countries (especially among term infants) [105], studies from developing countries present a different picture. The most striking finding in the review was the significantly lower rates of GBS sepsis in South Asia, Central Asia, East Asia, Middle East, and the Pacific, in contrast to the relatively high rate reported from Africa (Table 2–2).

It is unclear why neonates in many low-income and middle-income countries are rarely infected with GBS. The most important risk factor for invasive GBS disease in the neonate is exposure to the organism via the mother's genital tract. Other known risk factors include young maternal age, preterm birth, prolonged rupture of the membranes, maternal chorioamnionitis, exposure to a high inoculum of a virulent GBS strain, and a low maternal serum concentration of antibody to the capsular polysaccharide of the colonizing GBS strain [106]. In the United States, differences in GBS colonization rates have been identified among women of different ethnic groups that seem to correlate with infection in newborns.

In an attempt to understand the low rates of invasive GBS disease reported among neonates in many low-income and middle-income countries, Stoll and Schuchat [107] reviewed 34 studies published during 1980-1998 that evaluated GBS colonization rates in women. These studies reported culture results from 7730 women, with an overall colonization rate of 12.7%. Studies that used culture methods that were judged to be appropriate found significantly higher colonization rates than the studies that used inadequate methods (675 of 3801 women [17.8%] versus 308 of 3929 women [7.8%]). When analyses were restricted to studies with adequate methods, the prevalence of colonization by region was Middle East/North Africa, 22%; Asia/Pacific, 19%; sub-Saharan Africa, 19%; India/Pakistan, 12%; and Americas, 14%.

The distribution of GBS serotypes varied among studies. GBS serotype III, the most frequently identified invasive serotype in the West, was identified in all studies reviewed and was the most frequently identified serotype in one half of the studies. GBS serotype V, which has been recognized only more recently as a cause of invasive disease in developed countries [108], was identified in studies from Peru [109] and The Gambia [110]. Monitoring serotype distribution is important because candidate GBS vaccines are considered for areas with high rates of disease.

With estimated GBS colonization rates among women in low-income and middle-income countries of about 18%, higher rates of invasive neonatal disease than have been reported would be expected. Low rates of invasive GBS disease in some low-income and middle-income countries may be due to lower virulence of strains, genetic differences in susceptibility to disease, as-yet unidentified beneficial cultural practices, or high concentrations of transplacentally acquired protective antibody in serum (i.e., a mother may be colonized, but have protective concentrations of type-specific GBS antibody).

In low-income and middle-income countries, where most deliveries occur at home, infants with early-onset sepsis often get sick and die at home or are taken to local health care facilities, where a diagnosis of possible sepsis may be missed, or where blood cultures cannot be performed. In these settings, there may be underdiagnosis of infection by early-onset pathogens, including GBS. In the WHO Young Infants Study [98], 1673 infants were evaluated in the first month of life; only 2 had cultures positive for GBS. The absence of GBS in this study cannot be explained by the evaluation of insufficient numbers of sick neonates (360 of the 1673 infants were <1 week of age).

Increasing evidence suggests that heavy colonization with GBS increases the risk of delivering a preterm infant with LBW [111]. Population differences in the prevalence

of heavy GBS colonization have been reported in the United States, where African Americans have a significantly higher risk of heavy colonization. If heavy colonization is more prevalent among women in low-income and middle-income countries and results in an increase in numbers of preterm infants with LBW, GBS-related morbidity may appear as illness and death related to prematurity. By contrast, heavy colonization could increase maternal type-specific GBS antibody concentrations, resulting in lower risk of neonatal disease. Further studies in low-income and middle-income countries are needed to explore these important issues.

## ANTIMICROBIAL RESISTANCE IN NEONATAL PATHOGENS

Increasing rates of resistance to antimicrobial agents among common pathogens involved in neonatal infections are being observed in low-income and middle-income countries [112]. Very limited published information is available, however, on antimicrobial resistance patterns among neonatal pathogens from community settings where a large proportion of births take place at home. A review identified only 10 studies during 1990-2007, including 2 unpublished, that contributed resistance data from community settings in low-income and middle-income countries, primarily regarding *Klebsiella* species, *E. coli*, and *S. aureus* [112]. Compared with data from hospital settings, resistance rates were lower in community-acquired infections. Greater than 70% of isolates of *E. coli* were resistant to ampicillin, and 13% were resistant to gentamicin. All *Klebsiella* species were resistant to ampicillin, and 60% were resistant to gentamicin [112]. Resistance to third-generation cephalosporins was uncommon, and methicillin-resistant *S. aureus* occurred rarely [112]. Additional data on antimicrobial resistance patterns of neonatal pathogens encountered in home-delivered infants are needed to develop evidence-based guidelines for management.

By contrast, a wealth of data from hospitals from low-income and middle-income countries show alarming antimicrobial resistance rates among neonatal pathogens in hospital nurseries. A large review showed that more than 70% of neonatal isolates from hospitals of low-income and middle-income countries were resistant to ampicillin and gentamicin—the recommended regimen for the management of neonatal sepsis [113,114]. Resistance was also documented against expensive second-line and third-line agents; 46% of *E. coli* and 51% of *Klebsiella* species were found to be resistant to the third-generation cephalosporin, cefotaxime [114]. Equally disturbing was the high prevalence of methicillin-resistant *S. aureus* isolates, especially in South Asia, where it constituted 56% of all isolates [114]. Also, pan-resistant *Acinetobacter* species infections are widely reported [115,116]. In these settings with constrained resources, many of these multidrug-resistant pathogens are untreatable.

## NOSOCOMIAL INFECTIONS

Hospitals in low-income and middle-income countries are ill-equipped to provide hygienic care to vulnerable newborn infants. A review of the rates of neonatal infections among hospital-born infants in low-income and middle-income countries found the rates to be 3 to 20 times higher than observed in industrialized countries [114]. A high proportion of infections in the early neonatal period were due to *Klebsiella* species, *Pseudomonas* species, and *S. aureus*, rather than organisms typically associated with the maternal birth canal, suggesting acquisition from the hospital environmental, rather than the mother [114]. Overall, gram-negative rods were found to be predominant, constituting 60% of all positive cultures from newborns. *Klebsiella* species were found to be the major pathogens, present in 23% of cases, followed by *S. aureus* (16.3%) and *E. coli* (12.2%) [114].

High nosocomial infection rates observed among hospital-born infants in low-income and middle-income countries are attributable to lack of aseptic delivery and hand hygiene; lack of essential supplies such as running water, soap, and gloves; equipment shortages; lack of sterilization facilities; lack of knowledge and training regarding adequate sterilization; overcrowded and understaffed health facilities, and inappropriate and prolonged use of antibiotics [114].

## HOSPITAL INFECTION CONTROL

Lack of attention to infection control increases the newborn's risk of acquiring a nosocomial pathogen from the hospital environment [114]. Urgent attention to improving infection control practices in hospitals that care for mothers and newborns is required if survival gains from promoting institutional delivery are to be fully realized. Several cost-effective strategies to reduce infection transmission in hospitals of low-income and middle-income countries have been discussed in a review of hospital-acquired neonatal infections [114].

Hand hygiene remains the most important infection control practice. In many low-income and middle-income countries, hospital delivery wards and nurseries lack sinks and running water, however. For such settings, alcohol-based hand rubs are an attractive option. Several studies have shown the efficacy of use of hand rubs by hospital staff in reducing rates of colonization and infection among neonates [117,118]. Although commercially available alcohol-based hand gels are expensive, costs may be offset by significant reduction in nosocomial infections. Also, low-cost solutions can be prepared by hospital pharmacies by combining 20 mL of glycerine, sorbitol, glycol, or propylene with 980 mL of greater than 70% isopropanol [114]. Addition of 0.5% chlorhexidine prolongs the bactericidal effect, but increases expense [114].

Aseptic technique during intrapartum care for the mother and sterile cord cutting are other important areas of intervention. Reducing the number of vaginal examinations reduces the risk of chorioamnionitis. A systematic review of the use of vaginal chlorhexidine treatment included two large, nonrandomized, nonblinded hospital-based trials from Malawi and Egypt that reported neonatal outcomes [119–121]. Both trials found that the use of 0.25% chlorhexidine wipes during vaginal examinations and application of another wipe for the neonate soon after birth significantly reduced early neonatal

deaths (in Egypt, 2.8% versus 4.2% in intervention versus control groups, $P = .01$) and neonatal mortality caused by infections (in Malawi, odds ratio 0.5, 95% confidence interval [CI] 0.29-0.88; in Egypt, 0.22% versus 0.84% in intervention versus control groups, $P = .004$) [122,123]. A hospital-based trial from South Africa found no impact, however, of maternal vaginal and newborn skin cleansing with chlorhexidine on rates of neonatal sepsis or the vertical acquisition of potentially pathogenic bacteria among neonates [124].

Topical application of emollients that serve to augment the barrier for invasion of pathogenic microbes through immature skin of premature infants has also shown promise. Daily applications of sunflower seed oil in very premature infants hospitalized in Bangladesh and Egypt have been shown to reduce nosocomial infections and mortality [125–127].

Appropriate measures are also needed to address infection transmission that may occur through reuse of critical items that come into contact with sterile body sites, mucous membranes, or broken skin. Improper sterilization and defective reprocessing of these items has been associated with higher rates of *Pseudomonas* infections in a study from Indonesia [128]. A study from Mexico identified several faults in the reprocessing chain, such as inadequate monitoring of sterilization standards and use of inappropriate sterilization agents [129].

Fluid reservoirs such as those used in suctioning and respiratory care can also be a source of infection in critical care areas. Targeted respiratory tract care with focused education campaigns has been found to be effective in reducing infection rates in developing countries [130]. In the face of outbreaks, point sources of contamination, such as intravenous fluids and medications, must be investigated and eliminated. Systematic reviews have found no evidence of the benefit of routine gowning by health personnel or infant attendants in hospital nurseries [131].

Several studies have also examined the impact of “bundled” or packaged interventions in controlling hospital-acquired infections among children in developing countries. These packages include several infection control interventions such as use of alcohol-based hand rubs, bedside checklists to monitor adequate infection control practices, appropriate antibiotic use policies, simple algorithms for effective treatment of neonatal sepsis, decreasing the degree of crowding in wards, increase in the number of infection control nurses, and establishing guidelines for appropriate handling of intravenous catheters and solutions. Although the results from these studies have varied in the degree of success, they all have reported decreases in nosocomial infections through implementation of such interventions [132].

# NEONATAL INFECTIONS

## ACUTE RESPIRATORY INFECTIONS

Onset of pneumonia in neonates may be early (acquired during birth from organisms that colonize or infect the maternal genital tract) or late (acquired later from organisms in the hospital, home, or community). Although only a few studies of the bacteriology of neonatal pneumonia have been performed, the findings suggest that organisms causing disease are similar to organisms that cause neonatal sepsis [133,134]. The role of viruses in neonatal pneumonia, especially in low-income and middle-income countries, is unclear. More recent studies from developed countries suggest that viruses, including respiratory syncytial virus, parainfluenza viruses, adenoviruses, and influenza viruses, contribute to respiratory morbidity and mortality, especially during epidemic periods [135,136]. Maternal influenza vaccination during pregnancy in Bangladesh reduced febrile respiratory illnesses in their young infants by one third compared with infants of mothers not receiving influenza vaccine, suggesting an important role for influenza viruses in neonatal acute respiratory infections (ARIs) [137].

Because of similarities in presentation, pneumonia in neonates is very difficult to differentiate from neonatal sepsis or meningitis, and all three diseases are often grouped under one category and treated similarly. Assessing the true burden of neonatal respiratory infections is very difficult. In a review of the magnitude of mortality from ARI in low-income and middle-income countries, Garenne and coworkers [138] estimated that 21% of all ARI deaths in children younger than 5 years occur in the neonatal period (1254 of 6041 ARI deaths in 12 countries). In a carefully conducted community-based study in rural India published in 1993, Bang and associates [139] determined that 66% of ARI deaths in the first year of life occurred in the neonatal period.

It is difficult to determine the incidence of neonatal ARIs in low-income and middle-income countries because many sick neonates are never referred for medical care. In a large community-based study of ARIs in Bangladeshi children, the highest incidence of ARIs was in children younger than 5 months of age [137]. In the study by Bang and associates [139], there were 64 cases of pneumonia among 3100 children (incidence of 21 per 1000), but this finding underestimates the true incidence because it was known that many neonates were never brought for care. A community-based study conducted by English and colleagues [47] in Kenya found the incidence of pneumonia to be 81 per 1000 for children younger than 2 months. The risk of pneumonia and of ARI-related death increases in infants who have LBW or are malnourished and in infants who are not breast-fed [140,141]. In a study of infants with LBW in India [142] in which infants were visited weekly and mothers queried about disease, there were 61 episodes of moderate to severe ARI among 211 infants with LBW and 125 episodes among 448 infants with normal birth weight. Although 33% of episodes of ARI occurred in infants with LBW, 79% of the deaths occurred in this weight group.

Management of pneumonia in neonates follows the same principles as management of neonatal sepsis because the presentation is difficult to distinguish clinically from sepsis. A respiratory rate greater than 60/min in an infant younger than 2 months has been proposed as a sensitive sign of serious illness and possible pneumonia by WHO, but concerns about low specificity secondary to conditions such as transient tachypnea of the newborn and upper respiratory infections remain to be addressed [143].

## DIARRHEA

Although diarrheal diseases are important killers of infants younger than 1 year, most deaths resulting from diarrhea during infancy occur in infants 6 to 12 months old [144,145]. Worldwide, only 3% of deaths in the neonatal period are attributed to diarrhea [3]. The high prevalence of breast-feeding in the first month of life in low-income and middle-income countries most likely protects breast-fed newborns from diarrhea [146,147].

Huilan and associates [148] studied the agents associated with diarrhea in children from birth to 35 months of age from five hospitals in China, India, Mexico, Myanmar, and Pakistan. The investigators studied 3640 cases of diarrhea, 28% of which occurred in infants younger than 6 months. Data on the detection of rotavirus, enterotoxigenic *E. coli*, and *Campylobacter* species were provided by age. Of these agents, 5% of isolates (17 of 323) were from neonates. Some studies report high diarrhea rates in the neonatal period, however. Black and colleagues [149] performed community studies of diarrheal epidemiology and etiology in a periurban community in Peru. The incidence of diarrhea was 9.8 episodes per child in the first year of life and did not differ significantly by month of age (0.64 to 1 episode per child-month). Mahmud and colleagues [150] prospectively followed a cohort of 1476 Pakistani newborns from four different communities. Of infants evaluated in the first month of life, 18% (180 of 1028) had diarrhea.

Although most infants in low-income and middle-income countries are born at home, infants born in hospitals are at risk for nosocomial diarrheal infections. Aye and coworkers [151] studied diarrheal morbidity in neonates born at the largest maternity hospital in Rangoon, Myanmar. Diarrhea was a significant problem, with rates of 7 cases per 1000 live births for infants born vaginally and 50 per 1000 for infants delivered by cesarean section. The difference in diarrhea rates was attributed to the following: Infants born by cesarean section remained hospitalized longer, were handled more by staff members and less by their own mothers, and were less likely to be exclusively breast-fed.

Rotavirus is one of the most important causes of diarrhea among infants and children worldwide, occurring most commonly in infants 3 months to 2 years. In low-income and middle-income countries, most rotavirus infections occur early in infancy [152,153]. There are few reports of rotavirus diarrhea in newborns [154]. In most cases, neonatal infection seems to be asymptomatic, and neonatal infection may protect against severe diarrhea in subsequent infections [155–157]. Neonates are generally infected with unusual rotavirus strains that may be less virulent and may serve as natural immunogens [158]. Exposure to the asymptomatic rotavirus I321 strain in particular has been shown to confer protection against symptomatic diarrheal episodes caused by rotavirus among neonates [159].

Infection among neonates may be more common, however, than was previously thought. Cicirello and associates [158] screened 169 newborns at six hospitals in Delhi, India, and found a rotavirus prevalence of 26%. Prevalence increased directly with length of hospital stay. More recently, Ramani and colleagues [160] found the prevalence of rotavirus among neonates with gastrointestinal symptoms to be 55% in a tertiary hospital in south India. The high prevalence of neonatal infections in India (and perhaps in other countries with low resources) could lead to priming of the immune system and have implications for vaccine efficacy. Several community-based studies reviewed earlier presented data on diarrhea as a cause of neonatal death [161–170]. In these studies, diarrhea was responsible for 1% to 12% of all neonatal deaths. In 9 of the 10 studies, 70 of 2673 neonatal deaths (3%) were attributed to diarrhea. Although diarrhea is more common in infants after 6 months of age, it is a problem in terms of morbidity and mortality for neonates in low-income and middle-income countries.

## OMPHALITIS

In low-income and middle-income countries, aseptic delivery techniques and hygienic cord care have markedly decreased the occurrence of omphalitis, or umbilical infection. Prompt diagnosis and antimicrobial therapy have decreased morbidity and mortality in cases of omphalitis. Omphalitis continues to be an important problem, however, where clean delivery and hygienic cord care practices remain a challenge, particularly among the world's 60 million home births, which account for nearly half of all births, and for many facility-based births in settings with low resources [171,172]. The necrotic tissue of the umbilical cord is an excellent medium for bacterial growth. The umbilical stump is rapidly colonized by bacteria from the maternal genital tract and from the environment. This colonized necrotic tissue, in close proximity to umbilical vessels, provides microbial pathogens with direct access to the bloodstream. Invasion of pathogens via the umbilicus may occur with or without the presence of signs of omphalitis, such as redness, pus discharge, swelling, or foul odor [173,174].

Omphalitis is associated with increased risk of mortality [175]. Omphalitis may remain a localized infection or may spread to the abdominal wall, the peritoneum, the umbilical or portal vessels, or the liver. Infants who present with abdominal wall cellulitis or necrotizing fasciitis have a high incidence of associated bacteremia (often polymicrobial) and a high mortality rate [172,176,177].

Limited data are available on risk factors and incidence of umbilical infections from low-income and middle-income countries, especially from community settings [169,171,178–183]. Overall, incidence of omphalitis in hospital-based studies has ranged from 2 to 77 per 1000 hospital-born infants, with CFR ranging from 0% to 15%. Mullany and colleagues [174] defined clinical algorithms for identification of umbilical infections and reported a 15% incidence of mild omphalitis, defined as the presence of moderate redness (<2 cm extension of redness onto the abdominal skin at the base of the cord stump), and a 1% incidence of severe omphalitis, defined as severe redness with pus, among 15,123 newborn infants identified in rural Nepal through community-based household surveillance [173,178].

A key risk factor for development of omphalitis in the community included topical applications of potentially

unclean substances (e.g., mustard oil). Hand washing with the soap in the clean delivery kit by the birth attendant before assisting with the delivery, consistent hand washing by the mother, and the practice of skin-to-skin care reduced the risk of omphalitis. In Pemba, Tanzania, 9550 cord assessments in 1653 infants identified an omphalitis rate of 1%, based on a definition of moderate to severe redness with pus discharge, to 12%, based on the presence of pus and foul odor [171].

Microbiologic data on causes of omphalitis are particularly lacking. Güvenç and associates [182] identified 88 newborns with omphalitis at a university hospital in eastern Turkey over a 2-year period. Gram-positive organisms were isolated from 68% of umbilical cultures, gram-negative organisms were isolated from 60%, and multiple organisms were cultured in 28% of patients. Airede [179] studied 33 Nigerian neonates with omphalitis. Aerobic bacteria were isolated from 70%, and anaerobic bacteria were isolated from 30%. Of the aerobic isolates, 60% were gram-positive organisms, and polymicrobial isolates were common. Faridi and colleagues [181] in India identified gram-negative organisms more frequently than gram-positive organisms (57% versus 43%), but *S. aureus* was the most frequent isolate (28%). In a study from Papua New Guinea, umbilical cultures were performed in 116 young infants with signs suggestive of omphalitis. The most frequently isolated organisms were group A β-hemolytic streptococci (44%), *S. aureus* (39%), *Klebsiella* species (17%), *E. coli* (17%), and *Proteus mirabilis* (16%) [102]. In infants with omphalitis and bacteremia, *S. aureus*, group A β-hemolytic streptococci, and *Klebsiella pneumoniae* were isolated from both sites. In Thailand, postdischarge follow-up cultures from 180 newborns yielded a positive culture in all cases, most commonly for *Klebsiella* species (60%), *E. coli* (37%), *Enterobacter* species (32%), and *S. aureus* [184]. In Oman, cultures from 207 newborns with signs of omphalitis yielded a positive culture in 191 cases; 57% were positive for *S. aureus*, 14% were positive for *E. coli*, and 10% were positive for *Klebsiella* species [185]. Community-based data on etiology of omphalitis in low-income and middle-income countries are lacking.

The method of caring for the umbilical cord after birth affects bacterial colonization, time to cord separation, and risk for infection and mortality [186–188]. Hygienic delivery and postnatal care practices, including hand washing and clean cord care, are important interventions to reduce risk of omphalitis and death [10,188]. Clean birth kits, which package together items such as a sterile blade, sterile cord tie, and soap, are promoted in many settings, especially for home births, although evidence for impact of birth kits on reducing rates of omphalitis and neonatal mortality is limited [189–194]. WHO currently recommends the practice of clean cord care, although it is acknowledged that antiseptics might benefit infants in settings where harmful substances are traditionally applied [195].

There is little evidence for optimal cord care practices to prevent cord infections and mortality in the community, although it is generally agreed that application of antimicrobial agents to the umbilical cord reduces bacterial colonization [188]. The effect of such agents on reducing infection is less clear [120,121,186,188]. During a study of pregnancy in a rural area of Papua New Guinea, Garner and colleagues [196] detected a high prevalence of neonatal fever and umbilical infection, which were associated with the subsequent development of neonatal sepsis. They designed an intervention program for umbilical cord care that included maternal health education and umbilical care packs containing acriflavine spirit and new razor blades. Neonatal sepsis was significantly less frequent in the intervention group.

More recently, Mullany and associates [173] showed a 75% reduction (95% CI 47% to 88%) in severe umbilical cord infections and a 24% reduction (95% CI −4% to 55%) in all-cause neonatal mortality in a large ($N$ = 15,123) community-based trial of 4% chlorhexidine cord cleansing, applied once daily for 8 of the first 10 days of life, compared with dry cord care. In infants enrolled within the first 24 hours of life, mortality was significantly reduced by 34% (95% CI 5% to 54%) in the chlorhexidine cord cleansing group. In a third study arm, soap and water did not reduce infection or mortality risk compared with dry cord care. Chlorhexidine treatment delayed cord separation by about 1 day; however, this was not associated with increased risk of omphalitis [197]. Data are awaited from additional studies of the impact of chlorhexidine cord cleansing on neonatal mortality from Pakistan, Bangladesh, Zambia, and Tanzania.

## TETANUS

Neonatal tetanus, caused by *Clostridium tetani*, is an underreported "silent" illness. Because it attacks newborns in the poorest countries of the world in the first few days of life, often while they are still confined to home, because it has a high and rapid CFR (85% untreated) [198], and because the newborns have poor access to medical care, the disease may go unrecognized [199–201]. The surveillance case definition of neonatal tetanus is straightforward—the ability of a newborn to suck at birth and for the first few days of life, followed by inability to suck starting between 3 and 10 days of age, spasms, stiffness, convulsions, and death [14].

Neonatal tetanus is a completely preventable disease. It can be prevented by immunizing the mother before or during pregnancy or by ensuring a clean delivery, clean cutting of the umbilical cord, and proper care of the cord in the days after birth [10]. Clean delivery practices have additional benefits, including prevention of other maternal and neonatal infections in addition to tetanus. Tetanus threatens mothers and infants, and tetanus-related mortality is a complication of induced abortion and childbirth in unimmunized women [202]. Immunization of women with at least three doses of tetanus toxoid vaccine provides complete prevention against maternal and neonatal tetanus.

The Maternal and Neonatal Tetanus Elimination Initiative of United Nations Children's Fund (UNICEF), WHO, United Nations Population Fund, and other partners, established in 1999, has led to the vaccination of more than 90 million women of childbearing age against tetanus, either through vaccination campaigns or during routine antenatal care visits. During 2000-2009,

14 countries and 15 states in India eliminated tetanus. In 2008, 81 million doses of tetanus vaccine were administered to mothers through routine antenatal care. An estimated 74% of women of childbearing age in developing countries are now adequately protected from tetanus, associated with marked and rapid declines in global deaths attributed to tetanus, from an estimated 787,000 in 1988 to 215,000 in 1999 and 128,000 in 2004 [203]. Progress continues, although the elimination of maternal and neonatal tetanus remains a global goal.

## OPHTHALMIA NEONATORUM

Ophthalmia neonatorum, defined as purulent conjunctivitis in the first 28 days of life, remains a common problem in many low-income and middle-income countries. The risk of infection in the neonate is directly related to the prevalence of maternal infection and the frequency of ocular prophylaxis. Infants born in areas of the world with high rates of sexually transmitted diseases (STDs) are at greatest risk.

Data on incidence and bacteriologic spectrum from specific countries are limited. Although a wide array of agents are cultured from infants with ophthalmia neonatorum [204–206], *Neisseria gonorrhoeae* (the gonococcus) and *Chlamydia trachomatis* are the most important etiologic agents from a global perspective [205,207–212] and share similar mechanisms of pathogenesis. Infection is acquired from an infected mother during passage through the birth canal or through an ascending route. Infection caused by one agent cannot be distinguished from infection caused by another agent by clinical examination; both produce a purulent conjunctivitis. Gonococcal ophthalmia may appear earlier, however, and is typically more severe than chlamydial conjunctivitis. Untreated gonococcal conjunctivitis may lead to corneal scarring and blindness, whereas the risk of severe ocular damage is low with chlamydial infection. Without ocular prophylaxis, ophthalmia neonatorum develops in 30% to 42% of infants born to mothers with untreated *N. gonorrhoeae* infection [208,210,211] and in approximately 30% of infants exposed to *Chlamydia* [210].

A 5-year study from Iran showed *S. aureus* to be the major organism responsible for ophthalmia neonatorum [213]. Similar predominance of *S. aureus* has been reported from Argentina and Hong Kong [214,215]. The reasons for these differences in etiology are not well understood, and data from countries with the lowest resources are unavailable.

Strategies to prevent or ameliorate ocular morbidity related to ophthalmia neonatorum include (1) primary prevention of STDs, (2) antenatal screening for and treatment of STDs (particularly gonorrhea and *Chlamydia* infection), (3) eye prophylaxis at birth, and (4) early diagnosis and treatment of ophthalmia neonatorum [211]. For developing countries, eye prophylaxis soon after birth is the most cost-effective and feasible strategy in settings where STD rates are high. Eye prophylaxis is used primarily to prevent gonococcal ophthalmia. Primary prevention of STDs in low-income and middle-income countries is limited, although promotion of condom use has been successful in reducing STDs in some countries [216,217]. Screening women at prenatal and STD clinics and treating based on a syndromic approach (i.e., treat for possible infections in all women with vaginal discharge without laboratory confirmation) is cost-effective, but may lead to overtreatment of uninfected women and missed cases.

Eye prophylaxis consists of cleaning the eyelids and instilling an antimicrobial agent into the eyes as soon after birth as possible. The agent should be placed directly into the conjunctival sac (using clean hands), and the eyes should not be flushed after instillation. Infants born vaginally and by cesarean section should receive prophylaxis. Although no agent is 100% effective at preventing disease, the use of 1% silver nitrate solution (introduced by Credé in 1881) [218] dramatically reduced the incidence of ophthalmia neonatorum. This inexpensive agent is still widely used in many parts of the world. The major problems with silver nitrate are that it may cause chemical conjunctivitis in 50% of infants, and it has limited antimicrobial activity against *Chlamydia* [211,219,220]. In low-income and middle-income countries where heat and improper storage may be a problem, evaporation and concentration are particular concerns. Although 1% tetracycline and 0.5% erythromycin ointments are commonly used and are as effective as silver nitrate for the prevention of gonococcal conjunctivitis, these agents are more expensive and unavailable in many parts of the world. Silver nitrate seems to be a better prophylactic agent in areas where penicillinase-producing *N. gonorrhoeae* is a problem [221].

The ideal prophylactic agent for settings with low resources would have a broad antimicrobial spectrum and be available and affordable. Povidone-iodine is an inexpensive, nontoxic topical agent that is potentially widely available. More recent studies suggest that it may be useful in preventing ophthalmia neonatorum. A prospective masked, controlled trial of ocular prophylaxis using 2.5% povidone-iodine solution, 1% silver nitrate solution, or 0.5% erythromycin ointment was conducted in Kenya [222]. Of 3117 neonates randomly assigned, 13.1% in the povidone-iodine group versus 15.2% in the erythromycin group and 17.5% in the silver nitrate group developed infectious conjunctivitis ($P < .01$). The high rates of infection in this study despite ocular prophylaxis are striking. Although there was no significant difference among agents in prevention of gonococcal ophthalmia (≤1% for each agent), povidone-iodine was most effective in preventing chlamydial conjunctivitis. A 2003 study by the same group compared prophylaxis with 1 drop and with 2 drops of the povidone-iodine solution instilled in both eyes at birth in 719 Kenyan neonates. No cases of *N. gonorrhoeae* infection were identified. Double application did not change the rates of infection with *C. trachomatis* (4.2% and 3.9%) [223].

Although the antimicrobial spectrum of povidone-iodine is wider than that of the other topical agents [224], and antibacterial resistance has not been shown [156], published data on the efficacy of povidone-iodine against penicillinase-producing *N. gonorrhoeae* are not yet available. A solution of 2.5% povidone-iodine might also be useful as an antimicrobial agent for cord care—of relevance in the prevention of omphalitis (see earlier).

Another trial in Iran compared the efficacy of topical povidone-iodine with erythromycin as prophylactic agents for ophthalmia neonatorum compared with no prophylaxis [225]. Among 330 infants studied, ophthalmia neonatorum developed in 9% of neonates receiving povidone-iodine versus 18% of neonates receiving erythromycin and 22% of neonates receiving no prophylaxis. Further studies are needed to establish the safety and efficacy of povidone-iodine in low-income and middle-income countries.

The frequency of practice of ocular prophylaxis in low-income and middle-income countries is unknown. In consideration of the high rates of STDs among pregnant women in many countries with low resources, eye prophylaxis is an important blindness prevention strategy. For infants born at home, a single dose of antimicrobial agent for ocular prophylaxis could be added to birth kits and potentially distributed to trained birth attendants during antenatal care, although more information about the feasibility and acceptability of this approach is needed. The strategy of ocular prophylaxis is more cost-effective than early diagnosis and appropriate treatment. In areas of the world in which access to medical care is limited, and effective drugs are scarce or unavailable, it may be the only viable strategy.

No prevention strategy is 100% effective. Even with prophylaxis, 5% to 10% of infants develop ophthalmia. All infants with ophthalmia must be given appropriate treatment, even if they received prophylaxis at birth. A single dose of either ceftriaxone (25 to 50 mg/kg intravenously or intramuscularly, not to exceed 125 mg) or cefotaxime (100 mg/kg intravenously or intramuscularly) is effective therapy for gonococcal ophthalmia caused by penicillinase-producing *N. gonorrhoeae* and non–penicillinase-producing *N. gonorrhoeae* strains [221]. Gentamicin and kanamycin also have been shown to be effective therapeutic agents and may be more readily available in some settings. Rarely, gonococcal infection acquired at birth may become disseminated, resulting in arthritis, septicemia, and meningitis. Neonates with disseminated gonococcal disease require systemic therapy with ceftriaxone or cefotaxime (25 to 50 mg/kg once daily) or cefotaxime (25 mg/kg intramuscularly or intravenously twice daily) for 7 days (for arthritis or sepsis) or 10 to 14 days (for meningitis). If a lumbar puncture cannot be performed (and meningitis cannot be ruled out) in an infant with evidence of dissemination, the longer period of therapy should be chosen [221]. Infants with chlamydial conjunctivitis should receive a 2-week course of oral erythromycin (50 mg/kg per day in four divided doses). After the immediate neonatal period, oral sulfonamides may be used [221].

## HUMAN IMMUNODEFICIENCY VIRUS INFECTION

The Joint United Nations Programme on HIV/AIDS (UNAIDS) and WHO estimate that in 2007 approximately 33 million people worldwide were infected with human immunodeficiency virus (HIV), and new infections were occurring at a rate of approximately 2.7 million per year [226]. Most HIV infections occur in low-income and middle-income countries; more than 90% of infected individuals live in sub-Saharan Africa, Asia, Latin America, or the Caribbean. Women are particularly vulnerable to HIV infection; worldwide, approximately 50% of cases occur in women. The proportion of women infected with HIV has increased in many regions; women represent approximately 60% of HIV infections in sub-Saharan Africa. An estimated 370,000 children were infected with HIV in 2007, mostly by mother-to-infant transmission in utero, at the time of delivery, or through breast-feeding [226].

Because HIV increases deaths among young adults, the acquired immunodeficiency syndrome (AIDS) epidemic has resulted in a generation of AIDS orphans. In 2007, it was estimated that 15 million children younger than 15 years of age have been orphaned by AIDS, most in sub-Saharan Africa [226–228]. It is well known that maternal mortality increases neonatal and infant deaths, independent of HIV infection. Global estimates for 2007, including the number of people living with HIV/AIDS, the number newly infected, and total AIDS deaths, are presented in Table 2–3.

### Transmission—Reducing the Disparity between Low-Income and High-Income Countries

Risk factors for mother-to-infant transmission of HIV include maternal health and severity of disease, obstetric factors, maternal coinfection with other STDs, prematurity or LBW, and infant feeding practices (Table 2–4). In most developed countries, evidence-based interventions including use of antiretroviral drugs, elective cesarean section before the onset of labor and before rupture of membranes, and avoidance of breast-feeding have reduced vertical transmission of HIV to 1% to 2%, with virtual elimination of transmission in some settings [229–232]. Without interventions, it is estimated that 20% to 45% of infants may become infected [233]. Rates of transmission remain high in settings with low resources, where there has been limited progress in increasing services for the prevention of mother-to-infant transmission of HIV [234]. In 2001, United Nations member states committed to the goal of reducing the

**TABLE 2–3** Statistics on the World Epidemic of Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome (HIV/AIDS): 2007

| | Estimate | Range |
|---|---|---|
| All people living with HIV/AIDS | 33 million | 30.3-36.1 million |
| Adults living with HIV/AIDS | 30.8 million | 28.2-34 million |
| Women living with HIV/AIDS | 15.5 million | 14.2-16.9 million |
| Children living with HIV/AIDS | 2 million | 1.9-2.3 million |
| All people newly infected with HIV | 2.7 million | 2.2-3.2 million |
| Children newly infected with HIV | 0.37 million | 0.33-0.41 million |
| All AIDS deaths | 2 million | 1.8-2.3 million |
| Child AIDS deaths | 0.27 million | 0.25-0.29 million |

*Adapted from Report on the AIDS Epidemic. Geneva, WHO, UNAIDS, 2008.*

**TABLE 2–4** Risk Factors Associated with Mother-to-Infant Transmission of Human Immunodeficiency Virus (HIV)

| Risk Factor | Possible Mechanism of Mother-to-Infant Transmission of Infection |
|---|---|
| ***Maternal Health*** | |
| Advanced HIV disease | High viral load and low CD4 T cells |
| Primary HIV infection | High viral load; lack of immune response |
| No maternal antiretroviral treatment | High viral load |
| ***Obstetric Factors*** | |
| Vaginal delivery | Exposure to HIV-infected genital secretions |
| Episiotomies and vaginal tears | Exposure to HIV-infected blood |
| Instrumental deliveries | Exposure of breached infant skin to secretions containing HIV |
| Chorionic villus biopsy or amniocentesis | Increased risk of placental microtransfusion |
| Fetal electrode monitoring | Breach in infant skin and exposure to infected secretions |
| Prolonged rupture of fetal membranes | Prolonged exposure to HIV-infected secretions |
| Chorioamnionitis | Ascending infection |
| Low birth weight | Impaired fetal or placental membranes |
| Prematurity | Impaired fetal or placental membranes |
| ***Maternal Coinfection*** | |
| Malaria (placental malaria) | Increased viral load, disruption in placental architecture |
| HSV-2 | Increased plasma viral load, increased shedding of HIV in genital secretions, genital ulcers |
| Other STDs | Genital ulcerations and exposure to HIV-infected blood or genital secretions |
| ***Infant Feeding*** | |
| Breast-feeding | Mastitis, cell-free and cell-associated virus |
| Mixed feeding | Contaminated formula or water used in preparing formula may cause gastroenteritis leading to microtrauma to infant's bowel, which provides entry to HIV virus |
| ***Miscellaneous Factors*** | |
| Infant-mother HLA concordance | HLA molecules on the surface of HIV-infected maternal cells are recognized as "self" by cytotoxic T lymphocytes or NK cells of the infant and are less likely to be destroyed |
| Maternal HLA homozygosity | Increased viral load |
| Presence of CCR5 $\Delta32$ mutation in T cells of exposed infants | Decreased susceptibility to HIV infection |

*HLA, human leukocyte antigen; HSV-2, herpes simplex virus type 2; NK, natural killer; STDs, sexually transmitted diseases.*

proportion of infants infected with HIV by 50% by 2010 [235]; although progress has been made, this goal has not been achieved.

## Breast-Feeding and Human Immunodeficiency Virus

Although breast-feeding by HIV-positive mothers is discouraged in Europe and North America, where safe and affordable alternatives to breast milk are available, the issue of breast-feeding and HIV is much more complicated in developing countries, where breast-feeding has proven benefits and where artificial feeding has known risks. Benefits of breast-feeding include decreased risk of diarrhea and other infectious diseases, improved nutritional status, and decreased infant mortality [236,237]. Research conducted over 20 years has increased understanding of mother-to-infant transmission of HIV through breast milk [238–240]. Risk factors for transmission of HIV via breast milk include maternal factors (e.g., recent infection or advanced maternal disease, low CD4 counts, viral load in breast milk and plasma, mastitis or breast abscess, and duration of breast-feeding); infant factors (e.g., prematurity, oral thrush, and being fed breast milk and non–breast milk alternatives resulting in "mixed" infant feeding); and viral factors (viral load, clade C) [238]. Three interventions have been shown to reduce late mother-to-infant transmission via breast-feeding: complete avoidance of breast-feeding, exclusive breast-feeding rather than mixed feeding, and antiretroviral prophylaxis for the lactating mother and for the infant who is breast-feeding [238–241].

In 2009 WHO updated their recommendations on HIV and infant feeding to help decision makers in different countries develop their own policies regarding feeding practices in the context of HIV infection [241]. The statement addresses several issues: the human rights perspective, prevention of HIV infection in women, the health of mothers and children, and elements for establishing a policy on HIV status and infant feeding. The document recommends that the choice of feeding option should depend on the mother's individual circumstances. All HIV-infected mothers should be counseled about the risks and benefits of feeding options and supported in their choice. Exclusive breast-feeding is recommended for the first 6 months of life, introducing appropriate complementary foods thereafter, and continue breastfeeding for the

first 12 months of life. Breastfeeding should then only stop once a nutritionally adequate and safe diet without breast milk can be provided. In addition, antiretroviral therapy to prevent perinatal HIV transmission should be provided to the pregnant woman as early as the 14th week of gestation and then to her infant throughout the breastfeeding period. The document also emphasizes that information and education on mother-to-infant transmission of HIV should be directed to the general public and to affected communities and families. A major challenge will be to implement these policies in developing countries where the bulk of perinatal HIV infections occur and where resources to follow these guidelines are limited.

### Prevention of Human Immunodeficiency Virus Infection in Low-Income and Middle-Income Countries

Primary prevention of HIV infection among women of childbearing age is the most successful but most difficult way to prevent the infection of infants. Improving the social status of women, educating men and women, ensuring access to information about HIV infection and its prevention, promoting safer sex through condom use, social marketing of condoms, and treating other STDs that increase the risk of HIV transmission are potential strategies that have been successful in reducing HIV infection. A goal for health services in low-income and middle-income countries is to provide interventions to reduce sexual transmission of HIV, with special focus on reducing infections during pregnancy and among women who are breast-feeding, and to prevent unintended pregnancies among women infected with HIV.

### Prevention of Human Immunodeficiency Virus Transmission from an Infected Mother to Her Infant

#### Antiretroviral Strategies

The era of antiretroviral therapy to reduce vertical transmission of HIV began in 1994 with publication of the Pediatric AIDS Clinical Trials Groups (ACTG) Protocol 076 [242]. This trial, performed in the United States and France, showed that zidovudine administered orally to HIV-infected pregnant women with no prior treatment with antiretroviral drugs during pregnancy, beginning at 14 to 34 weeks of gestation and continuing throughout pregnancy, and then intravenously during labor to the mother, and orally to the newborn for the first 6 weeks of life, reduced perinatal transmission by 67.5%, from 25.5% (95% CI 18.4% to 32.5%) to 8.3% (95% CI 3.9% to 12.8%). The regimen was recommended as standard care in the United States and quickly became common practice. Studies have shown that various antiretroviral regimens among pregnant women can reduce mother-to-infant transmission of HIV. These studies have shown that it is feasible to provide antiretroviral therapy and prophylaxis to women in low-income and middle-income countries and substantially reduce mother-to-infant transmission throughout the world [234,243–245].

Antiretroviral therapy requires the identification of HIV-infected women early enough in pregnancy to allow them access to therapy. A system for voluntary, confidential HIV counseling and testing must be in place. In 2007, only 18% of pregnant women in low-income and middle-income countries where data were available had been tested for HIV, however, and only 33% of pregnant women infected with HIV were treated with antiretroviral drugs including therapy to prevent vertical transmission of HIV [234].

#### Cesarean Section

Meta-analyses of North American and European studies performed in the late 1990s found that elective cesarean section reduced the risk of mother-to-infant transmission of HIV by more than 50% [246,247]. For mothers on highly active antiretroviral therapy and with low viral loads, the benefits of delivery by cesarean section for reducing perinatal transmission of HIV are uncertain, especially in settings with low resources where risks of operative complications are high [248].

### Integrated Health Care Programs

Successful programs to reduce mother-to-infant transmission of HIV require integration with health care services for women and children. These programs provide early access to adequate antenatal care, voluntary and confidential counseling and HIV testing for women and their partners, antiretroviral drugs during pregnancy and delivery for HIV-positive women, improved care during labor and delivery, counseling for HIV-positive women regarding choices for infant feeding, and support for HIV-positive women with ongoing health care and antiretrovirals for life and follow-up for their infants (Table 2–5).

### Human Immunodeficiency Virus and Child Survival

Although there have been tremendous gains in child survival over the past 3 decades, with reductions worldwide in deaths resulting from diarrhea, pneumonia, and vaccine-preventable diseases [1,249], the AIDS epidemic threatens to undermine this dramatic trend in some countries in sub-Saharan Africa [250]. In sub-Saharan Africa, AIDS has become a leading cause of death among infants and children, although globally it causes only 3% of deaths in children younger than 5 years of age [1,249]. There is a complex link between increasing mortality of children younger than 5 years old and high rates of HIV prevalence in adults, related to mother-to-infant transmission of HIV and the compromised ability of parents who are ill themselves to care for young children [251].

With success of programs to prevent mother-to-infant transmission of HIV, increasing numbers of infants who are exposed to HIV but uninfected are being born [252]. A challenge for health care systems is to ensure that these infants have access to health care and remain healthy. Programs for HIV/AIDS prevention and treatment have been developed largely as vertical programs that now need to be linked to broader efforts to improve maternal, neonatal, and child health care in low-income and middle-income countries.

## TUBERCULOSIS

Tuberculosis affects 13.9 million people worldwide and remains a major global public health threat, causing the deaths of 0.5 million women annually [203]. After

**TABLE 2–5** Essential Services for High-Quality Maternal Care

| ***Routine Quality Antenatal and Postpartum Care for All Women Regardless of HIV Status*** |
|---|
| Health education; information on prevention and care for HIV and sexually transmitted infections including safer sex practices; and pregnancy including antenatal care, birth planning and delivery assistance, malaria prevention, optimal infant feeding, family planning counseling and related services |
| Provider-initiated HIV testing and counseling, including HIV testing and counseling for women of unknown status at labor and delivery or postpartum |
| Couple and partner HIV testing and counseling including support for disclosure |
| Promotion and provision of male and female condoms |
| HIV-related gender-based violence screening |
| Obstetric care, including history taking and physical examination |
| Maternal nutritional support |
| Counseling on infant feeding |
| Psychosocial support |
| Birth planning and birth preparedness (including pregnancy and postpartum danger signs), including skilled birth attendants |
| Tetanus vaccination |
| Iron and folic acid supplementation |
| Syphilis screening and management of sexually transmitted diseases |
| Risk reduction interventions for injecting drug users |
| ***Additional Services for Women Living with HIV*** |
| Additional counseling and support to encourage partner testing, adoption of risk reduction and disclosure |
| Clinical evaluation, including clinical staging of HIV disease |
| Immunologic assessment (CD4 cell count) where available |
| ART when indicated |
| Counseling and support on infant feeding based on knowledge of HIV status |
| Antiretroviral prophylaxis for prevention of mother-to-infant transmission of HIV provided during antepartum, intrapartum, and postpartum periods |
| Co-trimoxazole prophylaxis where indicated |
| Additional counseling and provision of services as appropriate to prevent unintended pregnancies |
| Supportive care, including adherence support |
| Additional counseling and provision of services as appropriate to prevent unintended pregnancies |
| Tuberculosis screening and treatment when indicated; preventive therapy (isoniazid prophylaxis) when appropriate |
| Advice and support on other prevention interventions such as safe drinking water |
| Supportive care including adherence support and palliative care and symptom management |
| ***Additional Services for All Women Regardless of HIV Status in Specific Settings*** |
| Malaria prevention and treatment |
| Counseling, psychosocial support, and referral for women who are at risk of or have experienced violence |
| Counseling and referral for women with a history of harmful alcohol or drug use |
| Deworming |
| Consider retesting late in pregnancy where feasible in generalized epidemics |
| ***Essential Postnatal Care for HIV-Exposed Infants and Young Children*** |
| Completion of antiretroviral prophylaxis regimen as necessary |
| Routine newborn and infant care including routine immunization and growth monitoring |
| Co-trimoxazole prophylaxis |
| Early HIV diagnostic testing and diagnosis of HIV-related conditions |
| Continued infant feeding counseling and support, especially after HIV testing and at 6 mo |
| Nutritional support throughout the first year of life including support for optimal infant feeding practices and provision of nutritional supplements and replacement foods if indicated |
| ART for children living with HIV, when indicated |
| Treatment monitoring for all children receiving ART |
| Isoniazid prophylaxis when indicated |
| Counseling on adherence support for caregivers |
| Malaria prevention and treatment where indicated |
| Diagnosis and management of common childhood infections and conditions and integrated management of childhood illness |
| Diagnosis and management of tuberculosis and other opportunistic infections |

*Continued*

**TABLE 2–5** Essential Services for High-Quality Maternal Care—cont'd

| ***Antiretroviral Regimens Recommended by World Health Organization (WHO) for Treating Pregnant Women and Preventing HIV Infection in Infants: Promoting More Efficacious Antiretroviral Regimens*** |
|---|
| WHO recommends ART for all pregnant women who are eligible for treatment. Initiation of ART in pregnant women addresses not only their health needs, but also significantly reduces HIV transmission to their infants. In addition, by securing the health of women, it also improves child well-being and survival |
| For pregnant women with HIV who do not yet require ART, antiretroviral prophylactic regimens are recommended for prevention of mother-to-infant transmission. Two regimens are recommended by WHO: Option A: MOTHER: Antepartum zidovudine (AZT, from as early as 14 weeks gestation); single dose nevirapine (NVP) at onset of labor; AZT and lamivudine (3TC) during labor and delivery and for 7 days postpartum. If mother received >4 weeks of AZT antepartum, can omit single dose NVP, AZT and 3TC. INFANT: Breastfeeding infants should receive daily NVP from birth until 1 week after all exposure to breastmilk has ended; Non-breastfeeding infants should receive AZT or NVP for 6 weeks. Option B: MOTHER: Triple antiretroviral drug therapy from 14 weeks gestation until 1 week after all exposure to breastmilk has ended. INFANT: Breastfeeding infants should receive daily NVP for 6 weeks and non-breastfeeding infants should receive AZT or NVP for 6 weeks. |

HIV/AIDS, tuberculosis is the second leading cause of death from infectious causes of women of childbearing age (15 to 44 years old), with an estimated 228,000 deaths occurring annually in this population [253]. Most worldwide disability-adjusted life years (99.4%) and deaths (99.6%) resulting from tuberculosis occur in low-income and middle-income countries [203,253]. Tuberculosis during pregnancy may have adverse consequences for the mother and infant, including increased risk of miscarriage, prematurity, LBW, and neonatal death [254–257]. Adverse perinatal outcomes are increased in mothers who have late diagnosis or incomplete or irregular therapy [254]. Ideally, diagnosis and treatment of tuberculosis in women should occur before pregnancy.

The lung remains the most common site of infection; however, the prevalence of extrapulmonary tuberculosis is increasing. Although congenital tuberculosis is rare, the fetus may become infected by hematogenous spread in a woman with placentitis, by swallowing or aspirating infected amniotic fluid, or by direct contact with an infected cervix at delivery [257]. The most common route of infection of the neonate is through airborne transmission of *Mycobacterium tuberculosis* from an infected, untreated mother to her infant. Infected newborns are at particularly high risk of developing severe disease, including fulminant septic shock with disseminated intravascular coagulation and respiratory failure [257,258].

The resurgence of tuberculosis and the increased risk of tuberculosis among individuals who are infected with HIV are well known. In areas where HIV is endemic, tuberculosis rates are increasing [259,260]. Pregnant women who are coinfected with HIV may be at increased risk for placental or genital tuberculosis, resulting in an increased risk of transmission to the fetus [261]. Additionally, neonates born with tuberculosis/HIV coinfection have been shown to be at higher risk of severe, rapidly progressive HIV disease [262]. In areas of the world where tuberculosis and HIV are endemic, the key to preventing neonatal tuberculosis is early identification of maternal tuberculosis and HIV serostatus, based primarily on maternal history and relevant investigations of the mother and newborn [263].

## MALARIA

From a global perspective, malaria is one of the most important infectious diseases. Half of the world's population live in areas with malaria risk. The disease is mainly confined to poorer tropical areas of Africa, Asia, and Latin America. An estimated 85% of all malaria deaths in 2006 occurred in children younger than 5 years old, amounting to 760,000 deaths in children younger than 5 years [264]. Countries in sub-Saharan Africa account for more than 90% of malaria cases and 88% of malaria cases among children younger than 5 years [264]. Each year, approximately 24 million African women become pregnant in malaria-endemic areas and are at risk for malaria during pregnancy [265]. Four species of the malaria parasite infect humans: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, and *Plasmodium malariae*. *P. falciparum* is responsible for the most severe form of disease and is the predominant parasite in tropical Africa, Southeast Asia, the Amazon area, and the Pacific. Groups at greatest risk for severe disease and death are young nonimmune children, pregnant women (especially primigravidas), and nonimmune adults [266].

### Malaria in Pregnancy

Preexisting levels of immunity determine susceptibility to infection and severity of disease [265–269]. In areas of high endemicity or high stable transmission, where there are high levels of protective immunity, the effects of malaria on the mother and fetus are less severe than in areas where malaria transmission is low or unstable (i.e., sporadic, periodic). It is unclear why pregnant women (even with preexisting immunity) are at increased risk for malaria. The most severe maternal complications (cerebral malaria, pulmonary edema, renal failure) occur in women previously living in nonendemic areas who have little or no immunity and are most frequent with infections caused by *P. falciparum*. Severe malaria may result in pregnancy-related maternal death.

Malaria parasitemia is more common, and the parasite burden tends to be higher in pregnant than in nonpregnant women [267,268]. This increase in prevalence and density of parasitemia is highest in primiparous women and decreases with increasing parity [268]. The greater severity in primiparous women from endemic areas seems to be attributable in part to a pregnancy-restricted *P. falciparum* variable surface protein present on parasitized erythrocytes; because primiparous women have not been previously exposed to this antigen, they lack immunity to it, allowing this protein to bind to placental chondroitin sulfate and parasitized erythrocytes to become sequestered in the placenta [270]. The parasite burden is

highest in the second trimester and decreases with increasing gestation [269,271,272]. The most important effects of malaria on pregnant women are severe anemia [267] and placental infection [265–269,273,274]. The prevalence of anemia can be 78%, and anemia is more common and more severe in primigravidas [273].

## Perinatal Outcome

Perinatal outcome is directly related to placental malaria. Malaria is associated with an increase in spontaneous abortions, stillbirths, preterm delivery, and intrauterine growth restriction, particularly in areas where malaria is acquired by nonimmune women [269,275,276]. Reported rates of fetal loss range from 9% to 50% [268]. The uteroplacental vascular space is thought to be a relatively protected site for parasite sequestration and replication [274,277]. Placental malaria is characterized by the presence of parasites and leukocytes in the intervillous space, pigment within macrophages, proliferation of cytotrophoblasts, and thickening of the trophoblastic basement membrane [273]. Placental infection may alter the function of the placenta, reducing oxygen and nutrient transport and resulting in intrauterine growth restriction, and may allow the passage of infected red blood cells to the fetus, resulting in congenital infection. In primigravidas living in endemic areas, placental malaria occurs in 16% to 63% of women, whereas in multigravidas, the prevalence is much lower at 12% to 33% [267,268].

The most profound effect of placental malaria is the reduction of birth weight [269,278,279]. *P. falciparum* and *P. vivax* infection during pregnancy are associated with a reduction in birth weight [280]. Steketee and associates [278] estimated that in highly endemic settings, placental malaria may account for approximately 13% of cases of LBW secondary to intrauterine growth restriction. In Africa, malaria is thought to be an important contributor to LBW in the almost 3.5 million infants with LBW born annually [281]. Malaria is one of the few preventable causes of LBW. Because LBW is a major determinant of neonatal and infant mortality in developing countries, malaria may indirectly increase mortality by increasing LBW [282].

## Congenital Malaria

Transplacental infection of the fetus also may occur. It is relatively rare in populations with prior immunity (0.1% to 1.5%) [267], but more common in nonimmune mothers. It is thought that the low rate of fetal infection concomitant with a high incidence of placental infection is due in part to protection from transplacental maternal antibodies [283,284].

The clinical characteristics of neonates with congenital malaria (i.e., malaria parasitemia on peripheral blood smear) include fever, respiratory distress, pallor, anemia, hepatomegaly, jaundice, and diarrhea. There is a high mortality rate with congenital infection [285]. The global burden of disease related to congenital malaria is unknown.

## Prevention and Treatment of Malaria in Pregnancy

Pregnant women living in malaria-endemic areas need access to services that can provide prompt, safe, and effective treatment for malaria. Among at-risk pregnant populations in areas with stable or high transmission, WHO recommends that malaria control strategies include antenatal care, at least two doses of intermittent preventive treatment with sulfadoxine-pyrimethamine during the second and third trimesters, early and consistent use of insecticide-treated bednets during pregnancy through the postpartum period, effective case management of malaria, and screening and treatment of anemia frequently resulting from malaria infection [286,287]. In areas with low transmission, case management is emphasized [287].

### *Prophylaxis and Treatment Using Antimalarial Drugs*

Chloroquine, the safest, cheapest, and most widely available antimalarial drug, has been the agent of choice for the prevention and treatment of malaria in pregnancy [288]. In all areas where *P. falciparum* is prevalent, the parasite is at least partially resistant to chloroquine, however, and resistance to sulfadoxine-pyrimethamine, the first-line drug for intermittent preventive treatment in pregnancy, is increasing [289,290]. There are a limited number of safe and effective antimalarials available for use in pregnancy. For a drug to be considered safe, it must be safe for the mother, safe for the fetus, and ideally safe for the breast-feeding infant [288,291]. New drug development has been impeded by the fact that pregnant women have been excluded for ethical reasons from drug development programs because of the justified fear of risks to the fetus [292,293].

A 2002 systematic review of prevention versus therapy in pregnant women examined studies on the effectiveness of prompt therapy for malaria infection, prophylaxis with antimalarial drugs to prevent infection, and reduced exposure to mosquito-borne infection by using insecticide-treated bednets [294]. Chemoprophylaxis is associated with reduced maternal disease, including anemia and placental infection. One study found that the incidence of placental malaria is reduced by prophylaxis, even when chloroquine is used in areas with chloroquine-resistant malaria [295]. In addition, a large systematic review showed prophylaxis to have a positive effect on birth weight, risk of preterm delivery, and neonatal mortality (relative risk [RR] 0.73, 95% CI 0.53 to 0.99) [296].

A major problem with chemoprophylaxis and prompt therapy for known or suspected infection is that it is often difficult to deliver services to pregnant women, especially women who live in areas remote from health centers. Intermittent preventive treatment involves two or three doses of a safe and effective antimalarial given to women in malaria-endemic areas with the presumption that they are at high risk of malaria infection. Studies from Africa have shown that intermittent preventive treatment can reduce the incidence of malaria and its adverse consequences [297,298]. These interventions are particularly important and cost-effective in pregnancy and have been estimated to reduce all-cause neonatal mortality by 32% [10,299,300]. In 2000, WHO recommended intermittent preventive treatment with sulfadoxine-pyrimethamine in malaria-endemic areas where *P. falciparum* is resistant to chloroquine and sensitive to sulfadoxine-pyrimethamine

[301]. This drug is effective in a single dose, is not bitter, and is relatively well tolerated. In areas where malaria transmission is lower and *P. vivax* and *P. falciparum* are a problem, finding an appropriate drug regimen is more difficult [302]. In these areas and where *P. falciparum* is resistant to sulfadoxine-pyrimethamine, further research on the safety and efficacy of alternative antimalarial drugs for prevention and treatment of malaria in pregnancy, including artemisinin-based combination therapies, is urgently needed [293].

### *Prevention Using Insecticide-Treated Bednets*

Although the benefits of antimalarial chemoprophylaxis have been established, poor compliance and increasing drug resistance have led to trials of alternative prevention strategies [303]. The use of insecticide-treated bednets has been successful in reducing childhood morbidity and mortality in malaria-endemic areas [304–306]. A systematic review of use of insecticide-treated bednets during pregnancy in Africa associated their use with a reduced risk of placental malaria in all pregnancies (RR 0.79, 95% CI 0.63 to 0.98), reduced risk of LBW (RR 0.77, 95% CI 0.61 to 0.98), and reduced risk of fetal loss in the first to fourth pregnancy (RR 0.67, 95% CI 0.47 to 0.97) [307]. The use of social marketing and incentive initiatives such as voucher and discounted net programs have increased bednet coverage and use [308,309]. An additional benefit of bednet use is protection of the neonate, who almost always sleeps with the mother in these settings [308]. A pooled analysis of studies of insecticide-treated bednet use in early childhood found a reduction in all-cause child mortality associated with the use of insecticide-treated bednets (RR 0.82, 95% CI 0.76-0.89) [15]. Although there is clear evidence of the impact of insecticide-treated bednets in Africa, further data are needed from trials of insecticide-treated bednets in Latin America and Asia and areas of high *P. vivax* transmission [307].

### *Malaria Control Strategies and Challenges*

Comprehensive malaria prevention and treatment strategies implementing the interventions recommended by WHO can have dramatic effects on child health outcomes. A program that achieved high coverage of multiple malaria control measures in Equatorial Guinea was associated with reduced prevalence of malaria infection (odds ratio 0.31, 95% CI 0.2 to 0.46) and led to an overall reduction in mortality in children younger than 5 years from 152 per 1000 to 55 per 1000 births (hazard ratio 0.34, 95% CI 0.23-0.49) [310].

Studies have shown an association between malaria and HIV in pregnancy with an increase in the risk of maternal malaria and of placental malaria in HIV-positive mothers, although the influence of malaria on the clinical course of HIV infection remains unclear [311–313]. There is some suggestion that coinfection with malaria and HIV infection in pregnancy may be linked with increased mother-to-infant transmission of HIV, perinatal and early infant mortality, and morbidity after the neonatal period [314,315]. Intermittent preventive treatment with sulfadoxine-pyrimethamine is less effective in preventing malaria in HIV-infected women than in women without HIV infection, underscoring the need for research to expand the arsenal of safe and effective antimalarials and to understand interactions between antimalarial and antiretroviral drugs [314]. Effective, practical, and well-tolerated strategies are needed to prevent and treat malaria in HIV-infected women.

## INDIRECT CAUSES OF NEONATAL DEATH RELATED TO INFECTION

In addition to direct infectious causes of neonatal deaths, a vast array of indirect causes contribute to infectious deaths in developing countries. These contributory factors have socioeconomic and medical roots. Sociocultural factors include poverty; illiteracy; low social status of women; lack of political power (for women and children) and lack of will in individuals who have power; gender discrimination (for mother and neonate); harmful traditional or cultural practices; poor hygiene; lack of clean water and sanitation; the cultural belief that a sick newborn is doomed to die, and that the family is powerless to alter fate; the family's inability to recognize danger signs in the newborn; inadequate access to high-quality medical care (because it is unavailable or unaffordable, or because of lack of transport for emergency care) or the lack of supplies or appropriate drugs; and maternal death [316–319]. Medical factors that may also contribute to an infectious neonatal death include poor maternal health; untreated maternal infections (including STDs, urinary tract infection, and chorioamnionitis); failure to immunize the mother fully against tetanus; unhygienic and inappropriate management of labor and delivery; unsanitary cutting and care of the umbilical cord; failure to promote early and exclusive breast-feeding; and prematurity or LBW or both [316,317,320–322]. To promote change, families must be empowered and mobilized to identify illness and to seek care. Health care workers (of all levels) must know what to do and must have the resources to support needed therapy. Better maternal care—preventive and curative—is preventive medicine for the newborn.

Coordinated activities are needed to bring about change that is sustainable by countries on their own over the long-term. A multidisciplinary approach—bringing together people with different interests, from different backgrounds, different agencies, different government ministries—is needed to seek solutions to problems and to implement change at the local level. Finally, global acknowledgment is needed that this is the right thing to do (i.e., a moral imperative), and with this acknowledgment the long-term commitment of substantial funding to help provide needed services to countries with low resources and high maternal and neonatal mortality. A major remaining challenge is to link science and medicine with social solutions through a global commitment to long-term, long-lasting change so that improvements in maternal and newborn health can be achieved and sustained.

## STRATEGIES TO PREVENT AND TREAT INFECTION IN NEONATES

Strategies to prevent or reduce neonatal infections and to reduce morbidity and mortality in newborns in whom infection develops involve putting into practice what is

known and creating innovative ways to make these interventions feasible in a developing country context. Use of simple, cost-effective technologies that are potentially available and feasible for use in the community and at first-level health facilities could have a major impact in reducing morbidity and mortality related to neonatal infection. Public health, medical, and social interventions all have a role to play in reducing the global burden of neonatal infection. Several potential interventions are reviewed here (Table 2–6).

## MATERNAL IMMUNIZATION TO PREVENT NEONATAL DISEASE

There is growing interest in the possibility of using maternal immunization to protect neonates and very young infants from infection through passively acquired transplacental antibodies or breast milk antibodies, or both (for additional information, see Chapter 38) [323,324].

**TABLE 2–6** Interventions to Reduce Neonatal Infections or to Reduce Infection-Associated Mortality in Low-Income and Middle-Income Countries

| |
|---|
| ***Periconceptional Care*** |
| Folic acid supplementation to prevent neural tube defects (and associated risk of infectious morbidity and mortality) |
| ***Antenatal Care*** |
| Tetanus immunization |
| Maternal influenza immunization |
| Primary prevention of sexually transmitted disease, including HIV infection, through maternal education and safer sex using condoms |
| Diagnosis and treatment of sexually transmitted diseases (e.g., syphilis), urinary tract infection (including detection and treatment of asymptomatic bacteriuria), malaria, and tuberculosis |
| Intermittent presumptive treatment for malaria |
| Sleeping under insecticide-treated bednet |
| Balanced protein-energy supplements in populations with insecure food sources |
| ***Intrapartum and Delivery Care*** |
| Skilled maternal and immediate newborn care |
| Antibiotics for preterm premature rupture of membranes |
| Corticosteroids for preterm labor (to prevent respiratory distress syndrome and hyaline membrane disease) |
| Optimal management of complications including fever, premature rupture of membranes, and puerperal sepsis |
| Clean delivery |
| Clean cutting of umbilical cord and clean cord care |
| Immediate breast-feeding |
| ***Postnatal Care*** |
| Immediate, exclusive breast-feeding |
| Hand washing |
| Thermal care to prevent and manage hypothermia |
| Skin-to-skin care |
| Emollient therapy (e.g., sunflower seed oil for very preterm infants) |
| Case management for pneumonia |

*Data from Darmstadt et al [10,12], and Bhutta et al [15].*

Immunization of pregnant women with tetanus toxoid has dramatically reduced cases of neonatal tetanus and is the classic example of maternal immunization and subsequent passive immunization to protect the newborn and the mother. Because most IgG antibody is transported across the placenta in the last 4 to 6 weeks of pregnancy, maternal immunization to prevent neonatal disease through transplacental antibodies is most promising for term rather than preterm newborns because the former would have adequate antibody levels at birth. Boosting breast milk antibodies by immunizing the mother is a potential strategy for reducing infection in term and preterm infants.

Routine influenza vaccination is recommended for women who are or will be pregnant during the influenza season [325]. Despite the fact that no study to date has shown an increased risk of either maternal complications or adverse fetal outcomes associated with inactivated influenza vaccination [326], compliance remains poor. A study in Bangladesh[327] revealed a greater burden of influenza in infants than had been predicted and showed that maternal influenza vaccination provided significant protection to infants and their mothers. Vaccinating mothers against influenza reduced laboratory-proven influenza in their infants by 68% from birth to 6 months of age and reduced episodes of maternal influenza-like illnesses by 35%. To achieve protection, influenza vaccines would need to be administered during each pregnancy. This vaccination would require strengthening of current antenatal immunization programs, which have limited reach, and education on the benefits of the vaccine to overcome the general reluctance to intervene in healthy pregnant women.

Other vaccines currently being developed or field tested to reduce or prevent neonatal infection by maternal immunization include vaccines against GBS, *S. pneumoniae*, and *H. influenzae* [328–337]. Because most neonatal GBS disease—especially the most severe—occurs in the first hours of life, maternal immunization to provide passive protection to the neonate is a potentially important strategy. A problem with GBS vaccines has been poor immunogenicity, resulting in more recent interest in the potential of conjugate vaccines [338]. GBS polysaccharide-tetanus toxoid conjugates are safe in adults and elicit antibody levels above what is likely to be passively protective for neonates [331,332]. Multivalent vaccines, which could provide protection against multiple GBS serotypes, are particularly promising [330].

Pneumococcal polysaccharide vaccines have been administered safely to pregnant women [334,336]. A study from Bangladesh reported that pneumococcal vaccination during pregnancy increased type-specific IgG serum antibody in mothers and their infants [335]. Cord blood levels of antibody were about half those of the mothers, with IgG1 subclass antibodies preferentially transferred to the infants. The estimated antibody half-life in the infants was 35 days. Immunization increased breast milk antibody as well. In a study of the 23-valent pneumococcal vaccine given to women before pregnancy, neither mothers nor infants had significantly elevated pneumococcus-specific antibody at delivery [335]. The study in Bangladesh of the impact of maternal influenza vaccination on risk of

maternal and infant respiratory illness used vaccination of mothers with 23-valent polysaccharide vaccine for the control group [327]. If passive immunization does not interfere with active immunization of young infants, vaccination of pregnant women could potentially be used to prevent pneumococcal disease in early infancy; however, this requires further research.

Additional studies of the safety, efficacy, and effectiveness of immunizing pregnant women with specific vaccines are needed. Studies must address issues of safety to the mother, fetus, and young infant. Vaccines are not routinely tested for safety in pregnant women, so most safety data come from animal studies or postlicensure pregnancy registries and adverse event reporting systems. Based on accumulated evidence, vaccines against diphtheria, tetanus, and influenza have been recommended for use in pregnancy. Studies must assess protection against specific diseases (e.g., sepsis, pneumonia, meningitis) and protection against all causes of neonatal and infant mortality. Local epidemiology must also be considered because HIV and malaria can reduce the amount of antibody transferred to the fetus, decreasing the benefits of maternal immunization programs in highly endemic areas. The subsequent response of the infant to active immunization also must be evaluated, to ensure that passive immunization does not interfere with the infant's ability to mount an immune response. In low-income and middle-income countries, studies must be done in settings in which it is possible to maintain surveillance throughout infancy.

## NEONATAL IMMUNIZATION

Protection of young infants against vaccine-preventable diseases requires vaccines that are immunogenic in early life (for additional information, see Chapter 38) [339]. Bacillus Calmette-Guérin (BCG), hepatitis B, and oral poliovirus vaccine are currently given to neonates within the first days of life in many low-income and middle-income countries. The BCG vaccine, developed early in the 20th century, is a live attenuated strain of *Mycobacterium bovis*. WHO promotes the use of BCG in newborns to prevent tuberculosis, and this vaccine is widely used in developing countries in which tuberculosis is a common and potentially lethal disease. Although approximately 3 billion doses have been given, the efficacy of this vaccine is still debated. Vaccine efficacy in many prospective trials and case-control studies of vaccine use at all ages ranges from possibly harmful to 90% protective [340].

One meta-analysis of BCG studies in newborns and infants concluded that the vaccine was effective and reduced infection in children by more than 50% [341]. It was estimated that the 100 million BCG vaccinations given to infants in 2002 prevented nearly 30,000 cases of tuberculous meningitis (5th to 95th centiles, 24,063 to 36,192) in children during their first 5 years of life, or 1 case for every 3435 vaccinations (2771 to 4177), and 11,486 cases of miliary tuberculosis (7304 to 16,280), or 1 case for every 9314 vaccinations (6172 to 13,729) [342]. At a cost of US$2 to 3 per dose, BCG vaccination costs US$206 (US$150 to 272) per year of healthy life gained, considered highly cost-effective. BCG reduced the risk of pulmonary tuberculosis, tuberculosis meningitis, disseminated tuberculosis, and death from tuberculosis. Factors that may explain the variability of responses to BCG vaccination in different studies and populations include use of a wide variety of vaccine preparations, regional differences in environmental flora that may alter vaccine response, and population differences [323]. The safety of BCG in immunocompromised patients (e.g., patients with HIV infection) is of significant concern, and WHO has now made HIV infection in infants a full contraindication to BCG vaccination [343].

Hepatitis B vaccination of newborns has proved that neonatal immunization can prevent neonatal infections and their sequelae [344]. Studies from developed and developing countries have shown that hepatitis B vaccine administered in the immediate newborn period can significantly reduce the rate of neonatal infection and the development of a chronic hepatitis B surface antigen (HBsAg) carrier state [345]. The efficacy of vaccine alone (without hepatitis B immunoglobulin) has allowed developing countries that cannot screen pregnant women and do not have hepatitis B immunoglobulin to make a major impact in reducing the infection of newborns. WHO recommends that all countries include hepatitis B vaccine in their routine childhood immunization programs [346].

With the global problem of increasing antibiotic resistance, maternal and neonatal immunization have become even more important strategies to pursue. In low-income and middle-income countries, issues of vaccine cost, availability, and efficacy in the field are particularly pressing and are major barriers to the use of vaccines that are known to be safe and effective. Global Alliance for Vaccines and Immunisation (GAVI), established in 1999 with funding from the Bill and Melinda Gates Foundation, is working to address these issues. Since 2000, more than 200 million children have been immunized with vaccines funded by GAVI, and more than 3.4 million premature deaths have been averted [347].

## ANTENATAL CARE AND PREVENTION OF NEONATAL INFECTION

The care and general well-being of the mother are inextricably linked to the health of her newborn. Antenatal care can play an important role in the prevention or reduction of neonatal infections [348]. Preventive and curative interventions directed toward the mother can have beneficial effects on the fetus and newborn. Tetanus immunization of the pregnant woman is an essential component of any developing country's antenatal care program and, as discussed earlier, prevents neonatal tetanus [349,350]. The diagnosis and treatment of STDs—especially syphilis, gonorrhea, and chlamydial infection—can have a significant impact on neonatal morbidity and mortality [351,352]. In areas of the world in which syphilis is endemic, congenital syphilis may be an important cause of neonatal morbidity and mortality [353]. Antenatal treatment of gonorrhea and chlamydial infection can prevent neonatal infection with these agents—ophthalmia neonatorum (for gonorrhea and chlamydial infection), disseminated gonorrhea, and neonatal respiratory disease (for chlamydial infection) [351,352]. STDs and maternal urinary tract infection increase the mother's risk of

puerperal sepsis, with its associated increased risk of neonatal sepsis. In malaria-endemic areas, treatment of maternal malaria can have an impact on newborn health, particularly through a reduction in the incidence of LBW [354].

Antenatal care also is an important setting for maternal education regarding danger signs during pregnancy, labor, and delivery—especially maternal fever, prolonged or premature rupture of the membranes, and prolonged labor—and danger signs to watch for in the newborn. It is the time and place for the mother to plan where and by whom she will be delivered and for the health care worker to stress the importance of a clean delivery, preferably with a skilled birth attendant.

## INTRAPARTUM AND DELIVERY CARE AND PREVENTION OF NEONATAL INFECTION

It is universally recognized that poor aseptic techniques during labor and delivery, including performing procedures with unclean hands and unclean instruments and unhygienic cutting of the umbilical cord, are major risk factors for maternal and neonatal infections [348]. It is essential to promote safe and hygienic practices at every level of the health care system where women deliver (home, first-level health clinic, district or referral hospital). Proper management of labor and delivery can have a significant impact on the prevention of neonatal infection. It is important to emphasize the need for clean hands; clean perineum; clean delivery surface; clean instruments; clean cord care; avoidance of harmful traditional practices; prevention of unnecessary vaginal examinations; prevention of prolonged labor; and optimal management of pregnancy complications including prolonged rupture of the membranes, maternal fever, and chorioamnionitis or puerperal sepsis [355].

## POSTNATAL CARE AND PREVENTION OF NEONATAL INFECTION

The birth attendant is responsible for observation of the newborn at and after birth and deciding that the newborn is healthy and ready to be "discharged" to the care of the mother. It is important to link postpartum care of the mother with surveillance and care of the newborn. Postnatal visits should be used for health education and negotiation of improved household practices and to detect and treat the sick newborn and to evaluate the mother. Birth attendants need to be trained to identify problems in the newborn, to treat simple problems (e.g., skin infections), and to refer newborns with conditions that are potentially life-threatening (e.g., suspected sepsis). Birth attendants should provide all new mothers with breast-feeding support and give advice regarding personal hygiene and cleanliness and other prevention strategies, such as clean cord care, thermal care, and immunization. Improvement in domestic hygiene should be encouraged, including sanitary disposal of wastes, use of clean water, and hand washing, so that the newborn enters a clean home and is less likely to encounter pathogenic organisms. Community interventions need to be designed and modified to meet the needs of mothers and newborns in different settings in different countries with varying policies on the role of frontline workers in the recognition and management of infections.

Despite its importance, postnatal care is one of the most neglected aspects of maternal and newborn care in low-income and middle-income countries. Although numerous simple, low-cost preventive interventions are available that can avert a substantial proportion of deaths attributed to infections—including immediate and exclusive breast-feeding, thermal care, hand washing, clean cord care, and skin-to-skin care [8,10,12,15]—few data are available on coverage with postnatal care (i.e., a postnatal visit with a health care provider within 2 days of delivery). In 12 African countries, more recent Demographic Health Survey data indicated that less than 10% of newborns, on average, received an early postnatal care visit [356].

The importance of early postnatal care was highlighted in a study in Sylhet, Bangladesh, where, overall, a 34% reduction (95% CI 7% to 53%) in neonatal mortality was achieved through implementation of maternal and neonatal interventions aimed primarily at prevention and treatment of infections delivered by community health workers through antenatal and postnatal home visits [357]. Further analysis revealed, however, that a 64% reduction (95% CI 45% to 77%) in mortality was seen among the newborns who had an early postnatal home visit within the first 2 days of life, whereas no impact on mortality was found among the newborns who were visited only after the first 2 days [358]. Another study found that promotion of healthy, preventive household newborn care practices (e.g., birth preparedness, clean delivery, breast-feeding, clean cord and skin care, thermal care) through home visitation and community meetings by trained community health workers in a very high mortality setting in Uttar Pradesh, India, resulted in a 54% reduction (95% CI 40% to 65%) in all-cause neonatal mortality [359]. Serious infections seemed to be the most important cause of death that was averted.

## BREAST-FEEDING

The promotion of early and exclusive breast-feeding is one of the most important interventions for the maintenance of newborn health and the promotion of optimal growth and development [355]. Breast-feeding is especially important in developing countries, where safe alternatives to breast milk are often unavailable or too expensive. Poor hygiene and a lack of clean water and clean feeding utensils make artificial formula a significant vehicle for the transmission of infection. Breast milk has many unique anti-infective factors, including secretory IgA antibodies, lysozyme, and lactoferrin (for additional information, see Chapter 5). In addition, breast milk is rich in receptor analogues for certain epithelial structures that microorganisms need for attachment to host tissues, an initial step in infection [360]. Many studies have shown that breast-feeding reduces the risk of infectious diseases, including neonatal sepsis, diarrhea, and possibly respiratory tract infection [361–366], and that breast-feeding protects against infection-related neonatal and infant mortality [8,10,367–370].

The HIV epidemic has raised questions about the safety of breast-feeding in areas in which there is a high prevalence of HIV infection among lactating women [371–381]. HIV can be transmitted through breast-feeding. A major question for any setting is whether the benefits of breast-feeding outweigh the risk of postnatal transmission of HIV through breast milk [373]. For many areas of the world, where infectious diseases, especially diarrheal diseases, are a primary cause of infant death, breast-feeding, even when the mother is HIV-infected, remains the safest mode of infant feeding. As noted earlier, all HIV-infected mothers should be counseled, however, about the risks and benefits of feeding options and supported in their choice.

## MANAGEMENT OF NEONATAL INFECTION

If the mother develops a puerperal infection, the newborn requires special attention and should be treated for presumed sepsis [348]. Prolonged rupture of the membranes, maternal fever during labor, and chorioamnionitis are particular risk factors for early-onset neonatal sepsis and pneumonia [382–384]. Ideally, high-risk infants who are born at home should be referred to the nearest health care facility for observation and antibiotic therapy. In practice, this referral may be either impossible or unacceptable to the family, as evidenced by high rates of noncompliance with referral in many settings [27,357,359], and ways to deliver care to the mother and the newborn in the home must be developed and evaluated.

## IDENTIFICATION OF NEONATES WITH INFECTION

If untreated, infections in newborns can rapidly become severe and life-threatening. Early identification and appropriate treatment of newborns with infection are crucial to survival. In low-income and middle-income countries, where access to care may be limited, diagnosis and treatment are particularly difficult. Maternal and neonatal factors that increase risk of infection in the newborn must be recognized. These factors include maternal infections during pregnancy (STDs, urinary tract infection, others); premature or prolonged rupture of membranes; prolonged labor; fever during labor; unhygienic obstetric practices or cord care; poor hand-washing practices; prematurity or LBW; artificial feeding; and generally unhygienic living conditions [316,317,320].

In areas without sophisticated technology and the diagnostic help of laboratory tests and radiographic studies, treatment decisions must be made on the basis of the history and findings on physical examination. The WHO Young Infants Study was designed to identify clinical predictors of serious neonatal infections; this study enrolled more than 3000 sick infants younger than 2 months of age who presented to health facilities in Ethiopia, The Gambia, Papua New Guinea, and the Philippines [385]. In multivariable analysis, 14 signs were independent predictors of severe disease: reduced feeding ability, absence of spontaneous movement, temperature greater than 38° C, drowsiness or unconsciousness, a history of a feeding problem or change in activity, state of agitation, the presence of lower chest indrawing (retractions), respiratory rate greater than 60/min, grunting, cyanosis, a history of convulsions, a bulging fontanelle, and slow digital capillary refill. The presence of any one of these signs had a sensitivity for severe disease (sepsis, meningitis, hypoxemia, or radiologically proven pneumonia) of 87% and a specificity of 54%; reducing the list to nine signs reduced sensitivity only slightly (83%), but significantly improved specificity (62%) [385].

More recently, 8899 young infants who presented to health facilities in six countries (India, Bangladesh, Pakistan, Ghana, South Africa, Bolivia) with a complaint of illness were enrolled in a second Young Infant Clinical Signs Study. Seven signs were found to be associated with severe illness requiring referral level care in the first week of life: history of difficulty feeding, history of convulsions, movement only when stimulated, respiratory rate of 60 breaths/min or more, severe chest indrawing, and temperature of 37.5° C or greater or less than 35.5° C. These signs had a sensitivity and specificity of 85% and 75% in infants less than 1 week old. Studies in Bangladesh have sought to validate the ability of community health workers to use the clinical signs recommended by the WHO Young Infant Studies during routine household surveillance to identify neonates needing referral level care.

In Sylhet, 288 newborns were assessed independently for the presence of clinical signs suggestive of very severe disease by community health workers and by study physicians. Compared with the physician's gold standard assessment, community health workers correctly classified very severe disease in newborns with a sensitivity of 91%, specificity of 95%, and kappa value of 0.85 ($P < .001$) [386]. In Mirzapur, Bangladesh, classification of very severe disease by community health workers showed a sensitivity of 73%, a specificity of 98%, a positive predictive value of 57%, and a negative predictive value of 99% [387]. In addition to clinical signs, community health workers gathered historical information on neonatal illness. A history of a feeding problem, as reported by the mother to a physician, was significantly associated with the presence of a severe feeding problem (particularly a lack of ability to suck) as assessed by community health workers. Because assessing breast-feeding is complex, time-consuming, and difficult for male physicians owing to cultural sensitivity, a reported history may substitute for an observed feeding problem in the algorithm, substantially simplifying the assessment. Trained and supervised community health workers seem to be able to use a diagnostic algorithm to identify severely ill newborns with high validity.

## ANTIBIOTIC TREATMENT OF NEONATES WITH INFECTION

The drugs most frequently used at present to treat suspected severe neonatal infections are a combination of penicillin or ampicillin and an aminoglycoside (usually gentamicin) [388]. WHO continues to recommend that young infants (from birth to 2 months of age) with signs of severe infection should be referred for inpatient care and treated with intravenous broad-spectrum antibiotics—a combination of a benzyl penicillin and an aminoglycoside such as gentamicin for 10 to 14 days.

If 90% of neonates with infections received timely and appropriate antibiotic therapy, it is estimated that 30% to 70% of global neonatal deaths attributed to infections could be averted [10]. Most infants with suspected serious infections in developing countries do not currently receive adequate treatment, however; inpatient care is not feasible for most families either because treatment is available only in tertiary care facilities that are inaccessible or because hospitalization is unaffordable or unacceptable to families [27,357]. In many settings, placement and management of an intravenous line is impossible, and parenteral antibiotic therapy must be delivered by intramuscular injections. In this context, extended-interval gentamicin regimens have been recommended as the preferred mode of aminoglycoside dosing [389–391], and evidence is accumulating that procaine penicillin may be a feasible alternative to multiple daily dosing regimens with ampicillin [392].

Eliminating the need for multiple daily contacts with the patient to deliver antibiotics makes it more feasible for frontline workers in settings with low resources potentially to treat neonates with suspected infections, either at peripheral health facilities or possibly even in the home [392]. Further efforts are under way to identify even simpler antibiotic treatment regimens that require fewer injections over the course of treatment. Antibiotics available for treatment of serious neonatal infections in developing countries have been reviewed more recently [393,394].

Ideally, antibiotic therapy should be tailored to the specific microbiologic needs of a particular patient or, if patient-level data are unavailable, for the geographic region based on local surveillance data, especially if blood cultures are not performed and cannot be used to guide therapy, as is the case in most low-income and middle-income countries. In reality, surveillance data also are generally unavailable, however. In addition, issues related to drug supply, availability, quality, and cost must be addressed. The problem of antibiotic resistance is now recognized to be a global problem, and the emergence of antibiotic-resistant pathogens is particularly alarming in hospitals in countries with low resources. The widespread availability of antibiotics in many low-income and middle-income countries, even directly to families outside contact with the formal health system, and indiscriminate and inappropriate antibiotic use in the health and agriculture sectors contribute to this problem.

Appropriate treatment of neonatal infections is one of the most important child survival interventions [10]. In areas where it is impossible to deliver parenteral antibiotic therapy in a health facility, community-based case management is emerging as a viable alternative to facility-based care [10–12,27,357,386,387,395–399]. More recent data suggest that well-trained and supervised primary health care workers, including community health workers conducting routine household surveillance, are capable of identifying and treating sick newborns [386,387,400]. In a pooled analysis of five controlled trials of community-based management of neonatal pneumonia (four using co-trimoxazole, one using ampicillin or penicillin), all-cause neonatal mortality was reduced by 27% (95% CI 18% to 35%), and pneumonia-specific mortality was reduced by 42% (95% CI 22% to 57%) [401]. A 62% reduction in neonatal mortality was also shown in a nonrandomized controlled study in rural Maharashtra, India, in which village health workers conducted home visits and identified and treated neonates with suspected serious infections with a combination of oral co-trimoxazole and injectable gentamicin. CFR declined from 16.6% before the intervention to 2.8% after the intervention ($P < .05$).

Similarly, in a cluster randomized controlled trial in rural Sylhet, Bangladesh, community health workers identified sick newborns and referred them to a health facility for treatment. If the family refused referral, the community health workers provided treatment in the home with injectable procaine penicillin and gentamicin, resulting in a 34% reduction (95% CI 7% to 53%) in neonatal mortality compared with the control arm where the usual services of the Government of Bangladesh and various private providers were available. In Sylhet, although only 32% of referrals of sick newborns to the hospital by community health workers were complied with, another 42% accepted injectable antibiotic treatment at home, indicating that with the addition of home-based treatment, approximately three fourths of sick neonates received curative antibiotic treatment from qualified providers or community health workers. CFR for treatment of neonates with suspected serious infections was 14.2% at health facilities and 4.4% in the hands of the community health workers. After controlling for differences in background characteristics and illness signs among treatment groups, newborns treated by community health workers had a hazard ratio of 0.22 (95% CI 0.07 to 0.71) for death during the neonatal period and newborns treated by qualified providers had a hazard ratio of 0.61 (95% CI 0.37 to 0.99) compared with newborns who received no treatment or were treated by untrained providers [392].

## INTEGRATED MANAGEMENT OF NEONATAL ILLNESS

An integrated approach to the sick child, including the young infant, has been developed by WHO and UNICEF [402]. This strategy promotes prompt recognition of disease, appropriate therapy using standardized case management, referral of serious cases, and prevention through improved nutrition (breast-feeding of the neonate), and immunization. This approach stresses diagnosis using simple clinical signs, defined through the Young Infant Clinical Signs Studies, that can be taught to health care workers at all levels. The health care worker assesses the infant by questioning the mother and examining the infant; classifies the illness as serious or not; and determines if the infant needs urgent treatment and referral, specific treatment and advice, or only simple advice and home management. The importance of breast-feeding is stressed, and follow-up instructions are given. All young infants are checked for specific danger signs that equate with need for emergency care and urgent referral. Because the signs of serious bacterial infection in the newborn are not easily recognized, every young infant with danger signs is given treatment for a possible bacterial infection.

## MATERNAL EDUCATION AND SOCIOECONOMIC STATUS

Maternal education, literacy, and overall socioeconomic status are powerful influences on the health of the mother and the newborn [403–406]. Education of girls must be promoted and expanded so that women of reproductive age know enough to seek preventive services, understand the implications of danger signs during labor and delivery and in their newborns, and recognize that they must obtain referral care for obstetric or newborn complications. Improvements in education and socioeconomic status are linked. They may affect child health by allowing the mother a greater voice in the family with greater decision-making power, making her better informed about domestic hygiene, disease prevention, or disease recognition, or enhancing her ability to seek medical attention outside the home and to comply with medical advice.

## CONCLUSION

Neonatal infections cause a massive burden of mortality and morbidity, most of which occur in low-income and middle-income countries in settings characterized by high-risk household practices, poor care seeking and access to quality care, and weak health systems. Surveillance for infections is lacking, but limited data indicate that antibiotic resistance is increasing. Many preventive and curative interventions are available, however, which if implemented effectively at large scale could avert most neonatal deaths around the world secondary to serious infections. Development of new and adapted tools and technologies holds promise for expanding the availability and impact of interventions to prevent deaths secondary to infections. Implementation challenges continue to limit coverage with interventions, however. Renewed commitment is needed to deliver evidence-based interventions at the community level and at health facilities, integrated with maternal and child health programs.

## ACKNOWLEDGMENTS

The authors are grateful to Dr. Rachel Haws for her excellent assistance with article references and editing of the chapter.

CHAPTER 3

# Obstetric Factors Associated with Infections of the Fetus and Newborn Infant

**Amy J. Gagnon ✪ Ronald S. Gibbs**

## CHAPTER OUTLINE

Early-onset neonatal infections often originate in utero. Risk factors for neonatal sepsis include prematurity, premature rupture of the membranes (PROM), and maternal fever during labor (which may be caused by clinical intra-amniotic infection [IAI]). This chapter focuses on these major obstetric conditions. In addition to these three "classic" topics, we discuss information indicating that intrauterine exposure to bacteria is linked to major neonatal sequelae, including cerebral palsy, bronchopulmonary dysplasia, and respiratory distress syndrome (RDS).

DOI: 10.1016/B978-1-4160-6400-8.00003-1

## INTRA-AMNIOTIC INFECTION

Clinically evident intrauterine infection during the latter half of pregnancy develops in 1% to 10% of pregnant women and leads to increased maternal morbidity and perinatal morbidity and mortality. Generally, the diagnosis is clinically based on the presence of fever and other signs and symptoms, such as maternal or fetal tachycardia, uterine tenderness, foul odor of the amniotic fluid, and maternal leukocytosis. Although not invariably present, rupture of membranes or labor typically occurs in cases of clinically evident IAI. Older retrospective studies report rates of IAI of 1% to 2% [1]. Subsequent prospective studies report rates of 4% to 10% [2–5]. Numerous terms have been applied to this infection, including chorioamnionitis, amnionitis, intrapartum infection, amniotic fluid infection, and IAI. We use IAI to distinguish this clinical syndrome from bacterial colonization of amniotic fluid (also referred to as microbial invasion of the amniotic cavity) and from histologic inflammation of the placenta (i.e., histologic chorioamnionitis). When citing authors who use alternative expressions, however, we defer to their terminology.

IAI can refer to a histologic, subclinical, or clinical diagnosis. Histologic IAI is defined by infiltration of the fetal membranes by polymorphonuclear leukocytes and occurs much more often than clinically apparent infection. This diagnosis can be made in 20% of term deliveries and more than 50% of preterm deliveries [6]. Pettker and colleagues [7] evaluated the ability of microbiologic and pathologic examination of the placenta to diagnose IAI accurately and found that microbiologic studies of the placenta show poor accuracy to diagnose IAI (as defined by positive amniotic fluid cultures). They concluded that the presence of histologic chorioamnionitis is a sensitive, but not specific, test to diagnose intra-amniotic inflammation.

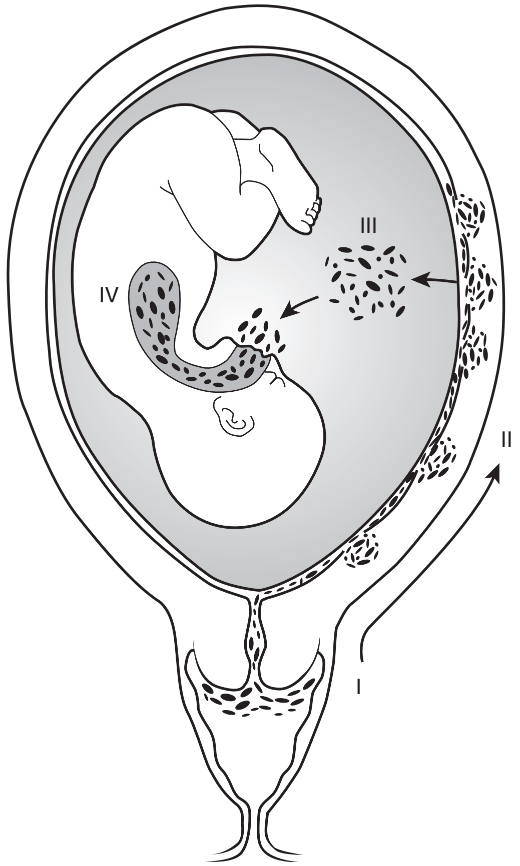

**FIGURE 3–1** Stages of ascending infection. *(Adapted from Romero R, Mazor M. Infection and preterm labor: pathways for intrauterine infections. Clin Obstet Gynecol 31:558, 1988.)*

## PATHOGENESIS

Before labor and membrane rupture, amniotic fluid is nearly always sterile. The physical and chemical barriers formed by intact amniotic membranes and cervical mucus are usually effective in preventing entry of bacteria. With the onset of labor or with membrane rupture, bacteria from the lower genital tract typically enter the amniotic cavity. With increasing interval after rupture of membranes, the numbers of bacteria can increase. This ascending route is the most common pathway for development of IAI [1]. In 1988, Romero and coworkers [1a] described four stages of ascending IAI (Fig. 3–1). Shifts in vaginal or cervical flora and the presence of pathologic bacteria in the cervix represent stage I. Bacterial vaginosis may also be classified as stage I. In stage II, bacteria ascend from the vagina or cervix into the decidua, the specialized endometrium of pregnancy. The inflammatory response here allows organisms to invade the amnion and chorion leading to chorioamnionitis. In state III, bacteria invade chorionic vessels (choriovasculitis) and migrate through the amnion into the amniotic cavity to cause IAI. When in the amniotic cavity, bacteria may gain access to the fetus through several potential mechanisms, culminating in stage IV; fetal bacteremia, sepsis, and pneumonia may result [8].

Occasional instances of documented IAI in the absence of rupture of membranes or labor support a presumed hematogenous or transplacental route of infection. IAI without labor and without rupture of membranes may be caused by *Listeria monocytogenes* [9–13]. Maternal sepsis caused by this aerobic gram-positive rod often manifests as a flulike illness and may result in fetal demise. In an outbreak caused by "Mexican-style" cheese contaminated with *Listeria*, several maternal deaths occurred [14]. Other virulent organisms, such as group A streptococci, may lead to a similar blood-borne infection [15].

IAI may develop as a consequence of obstetric procedures such as cervical cerclage, diagnostic amniocentesis, cordocentesis (percutaneous umbilical cord blood sampling), or intrauterine transfusion. The absolute risk is small with all these procedures. With cervical cerclage, data regarding infectious complications are sparse; reported rates range from 1% to 18%, with increasing rate with advanced dilation [16–18]. After diagnostic amniocentesis, rates of IAI range from 0% to 1% [19,20]. With intrauterine transfusion, infection is reported to develop in approximately 10%. Chorioamnionitis is a rare complication of chorionic villus sampling. Although IAI is very rare after percutaneous umbilical blood sampling, and the fetal loss rate accompanying this procedure is only 1% to 2%, infection is responsible for a high percentage of losses and may lead to life-threatening maternal complications [21].

Two large studies of risk factors for IAI identified characteristics of labor as the major risk factors by logistic regression analysis. These features included low parity, increased

number of vaginal examinations in labor, increased duration of labor, increased duration of membrane rupture, and internal fetal monitoring [1,4]. Other data from a randomized trial of active management of labor showed that chorioamnionitis occurs less frequently when labor management features early diagnosis of abnormalities and early intervention [5]. Although internal fetal monitoring is associated with IAI, it should be employed if it enables practitioners to diagnose and treat abnormalities more efficiently.

Risk factors for IAI have been stratified for term versus preterm pregnancies [22]. For patients at term with IAI, the study investigators observed, by logistic regression analysis, that the independent risk factors were membrane rupture for longer than 12 hours (odds ratio [OR] 5.81), internal fetal monitoring (OR 2.01), and more than four vaginal examinations in labor (OR 3.07). For preterm pregnancies, these three risk factors were identified again as being independently associated with IAI, but with differing ORs. Specifically, in the preterm pregnancies, membrane rupture for longer than 12 hours was associated with an OR of 2.49; internal fetal monitoring, OR of 1.42; and more than four examinations in labor, OR of 1.59. One interpretation of these data regarding risk factors among preterm pregnancies is that there was some other risk factor not detected in this survey. Additionally, meconium staining of the amniotic fluid has been associated with an increased risk of chorioamnionitis (4.3% versus 2.1%) [23]. Prior spontaneous and elective abortion (at <20 weeks) in the immediately preceding pregnancy also has been associated with development of IAI in the subsequent pregnancy (OR 4.3 and OR 4.0) [24].

In 1996, a multivariable analysis showed the importance of chorioamnionitis in neonatal sepsis [25]. The OR for neonatal sepsis accompanying clinical chorioamnionitis was 25, whereas for preterm delivery, membrane rupture for longer than 12 hours, endometritis, and colonization with group B streptococcus (GBS), an ORs all were less than 5.

Although Naeye had reported an association between recent coitus and development of chorioamnionitis defined by histologic study [26], further analysis of the same population refuted this association [27]. Other studies have not shown any relationship between coitus and PROM, premature birth, or perinatal death [28].

## MICROBIOLOGY

The cause of IAI is often polymicrobial, involving aerobic and anaerobic organisms. Sperling and colleagues [72] reported a microbiologic controlled study of amniotic fluid cultures from patients with IAI versus patients without IAI. Patients with IAI were more likely to have $10^2$ colony-forming units (CFU)/mL of any isolate, any number of high virulence isolates, and more than $10^2$ CFU/mL of a high-virulence isolate (e.g., GBS, *Escherichia coli*, and enterococci). The isolation of low-virulence organisms, such as lactobacilli, diphtheroids, and *Staphylococcus epidermidis*, was similar in the IAI and control groups [29]. Table 3–1 shows the most common amniotic fluid isolates found in more than 400 cases of IAI.

Although GBS and *E. coli* were isolated with only modest frequency (15% and 8%), they are strongly associated with either maternal or neonatal bacteremia. When GBS

**TABLE 3–1** Microbes Isolated in Amniotic Fluid from Cases of Intra-amniotic Infection*

| *Gardnerella vaginalis* | 24 |

*Data from references [13, 27, 28, 33], and [40]. See text.*

was found in the amniotic fluid of women with IAI, maternal or neonatal bacteremia was detected in 25% of the cases. When *E. coli* was found, maternal or neonatal bacteremia was detected in 33%. These rates of bacteremia are significantly higher ($P < .05$) than the 10% rate for all organisms and the 1% rate for anaerobes (see Chapter 2). Although *Gardnerella vaginalis* was isolated with high frequency, its pathogenic role is unclear. In a case-control study, *G. vaginalis* was isolated with similar frequencies in IAI and control cases (24 of 86 [28%] versus 18 of 86 [21%]), and there was no detectable maternal antibody response to this organism.

*Neisseria gonorrhoeae* rarely has been reported to cause amnionitis [30,31]. Data related to the role of *Chlamydia trachomatis* in infections of amniotic fluid are conflicting. Martin and coworkers prospectively studied perinatal mortality in women whose pregnancies were complicated by antepartum maternal *Chlamydia* infections [32]. Two of the six fetal deaths in the *Chlamydia*-positive group were associated with chorioamnionitis compared with one of eight in the control group. Wager and colleagues showed that the rate of occurrence of intrapartum fever was higher in patients with *C. trachomatis* infection (9%) than in patients without *C. trachomatis* isolated from the cervix (1%) [33]. These data must be interpreted with caution because of the limited number of patients and because the control group may not have been sufficiently similar to the infected group. *C. trachomatis* has not been isolated from amniotic cells or placental membranes of patients with IAI [34,35].

In a controlled study of IAI, 35% of amniotic fluid samples from 52 patients with IAI yielded *Mycoplasma hominis*, whereas only 8% of amniotic fluid samples from the 52 matched controls had *M. hominis* ($P < .001$). *Ureaplasma urealyticum* was isolated from the amniotic fluid from 50% of the infected and uninfected patients. *M. hominis* is present more commonly in the amniotic fluid of infected patients, but usually in association with other bacteria of

known virulence. In a subsequent study, *M. hominis* was found in the blood of 2% of women with IAI and with *M. hominis* in the amniotic fluid. The rate of serologic response was significantly greater than that in asymptomatic control women or infected women without IAI in the amniotic fluid ($P < .001$). These results suggest that the pathogenic potential of *M. hominis* is high.

Goldenberg and colleagues found that 23% of neonates who were born between 23 and 32 weeks of gestation had positive umbilical blood cultures for genital mycoplasmas (*U. urealyticum* and *M. hominis*) [36]. Patients with spontaneous preterm delivery had a significantly higher rate of blood cultures positive for *U. urealyticum* or *M. hominis* or both than patients with indicated preterm delivery (34.7% versus 3.2%; $P < .0001$) The earlier the gestational age at delivery, the more likely the culture was positive. In addition, newborns with a positive blood culture had a higher frequency of a neonatal systemic inflammatory response syndrome, higher serum concentrations of interleukin (IL)-6, and more frequent histologic evidence of placental inflammation than neonates with negative cultures.

The aforementioned studies support the idea that genital mycoplasmas can cause fetal and neonatal morbidity. Considering this notion, a crucial question is why genital mycoplasmas gain access to the amniotic cavity in some, but not most, pregnant women.

Pregnant women seem particularly susceptible to infection with *L. monocytogenes*, an organism that has caused regular outbreaks of infection often associated with contaminated cheeses and other dairy products. The infection is especially dangerous in immunocompromised hosts (fetuses, neonates, and immunocompromised children or adults). Several outbreaks of *L. monocytogenes*–associated febrile gastroenteritis have been reported among healthy adults, but only at doses of $10^5$ CFU or greater [37–40]. A study using rhesus monkeys as a surrogate for pregnant women indicated that oral exposure to $10^7$ CFU of *L. monocytogenes* resulted in about 50% stillbirths [41]. In 2002, an outbreak of listeriosis in the United States that was responsible for three stillbirths was linked to eating sliceable turkey deli meat [42].

Evidence has shown that maternal bacterial vaginosis is causally linked to IAI [43]. The evidence may be categorized as follows: (1) The microorganisms in bacterial vaginosis and in IAI are similar (anaerobes and mycoplasmas plus *G. vaginalis*), (2) bacterial vaginosis is associated with the isolation of organisms in the chorioamnion, and (3) bacterial vaginosis is associated with development of clinical chorioamnionitis in selected populations [44–46]. It has been shown that treatment of bacterial vaginosis in high-risk populations prenatally decreases the risk of chorioamnionitis and other pregnancy outcomes [47]. In the large trial of Maternal-Fetal Medicine Units Network of the National Institutes of Child Health and Development (NICHD), screening and treatment did not lead to benefit, however, either in the overall patient population or in the secondary analysis of women with prior preterm birth [48]. Subsequently, an American College of Obstetricians and Gynecologists Practice Bulletin on assessment of risk factors for preterm birth advocated that screening and treatment of high-risk or low-risk women would not be expected to reduce the overall rate of preterm birth [49]. In certain populations of high-risk women, such as women with prior preterm birth and bacterial vaginosis early in pregnancy, many experts still recommend treatment of bacterial vaginosis diagnosed early in pregnancy [50].

The role of viruses in causing IAI is unclear. Yankowitz and associates evaluated fluid from 77 mid-trimester genetic amniocenteses by polymerase chain reaction (PCR) assay for the presence of adenovirus, enterovirus, respiratory syncytial virus, Epstein-Barr virus, parvovirus, cytomegalovirus, and herpes simplex virus. Six samples were positive (three adenovirus, one parvovirus, one cytomegalovirus, and one enterovirus), and two resulted in pregnancy loss, one at 21 weeks (adenovirus) and one at 26 weeks (cytomegalovirus) [51]. More recently, primary or reactivated adeno-associated virus-2 infection (maternal IgM seropositivity) early in pregnancy was associated with spontaneous preterm delivery [52].

## DIAGNOSIS

Diagnosis of IAI requires a high index of suspicion because the clinical signs and symptoms may be subtle. Usual laboratory indicators of infection, such as positive stains for organisms or leukocytes and positive culture results, are found more frequently than clinically evident infection. Microorganisms are easily grown in culture from amniotic fluid or chorioamniotic membranes using standard techniques.

### Antepartum Criteria

The clinical criteria used to make the diagnosis of clinical IAI varies among centers, but often includes maternal fever, maternal tachycardia, fetal tachycardia, uterine tenderness, and foul-smelling amniotic fluid [2]. Maternal leukocytosis (peripheral white blood cell count >15,000/mm$^3$) supports the diagnosis of clinical IAI. The presence of a left shift (i.e., an increase in the proportion of neutrophils, especially immature forms) is particularly suggestive of clinical IAI. One caveat is that the recent administration of corticosteroids may cause a mild leukocytosis [53]. The increase is caused by demarginated mature neutrophils, however, and the presence of immature forms still suggests infection.

Other causes of fever in the parturient patient include epidural analgesia, concurrent infection of the urinary tract or other organ systems, dehydration, illicit drug use, and other rare conditions. The differential diagnosis of fetal tachycardia includes prematurity, medications, arrhythmias, and hypoxia. Possible causes of maternal tachycardia include drugs, hypotension, dehydration, anxiety, intrinsic cardiac conditions, hypothyroidism, and pulmonary embolism. Foul-smelling amniotic fluid and uterine tenderness, although more specific signs, occur in only a few cases. Bacteremia occurs in less than 10% of cases.

Direct examination of the amniotic fluid may provide important diagnostic information. Samples can be collected transvaginally by aspiration of an intrauterine pressure catheter, by needle aspiration of the forewaters, or by amniocentesis. Outside of research protocols, transabdominal amniocentesis is the most common technique.

Of the rapid diagnostic tests that evaluate IAI, amniotic fluid glucose is the most specific for predicting a positive amniotic fluid culture [54]. Kiltz and colleagues found that

an amniotic fluid glucose of less than or equal to 5 mg/dL had a positive predictive value of 90%, whereas a glucose of greater than 20 mg/dL had a negative predictive value of 98% [55]. With intermediate values (i.e., 14 to 15 mg/dL), the likelihood of a positive amniotic culture is 30% to 50%. Hussey and associates prospectively evaluated Gram stain and showed that it is 80% sensitive and 91% specific when a positive result is considered in the presence of white blood cells or bacteria [56]. These investigators concluded that the combination of Gram stain with amniotic fluid glucose level is superior to any individual test.

Amniotic fluid IL-6 is even more sensitive and specific than amniotic fluid glucose and Gram stain [57,58]. IL-6 is an immunostimulatory cytokine and a key mediator of fetal host response to infection. At the present time, this test is not typically available outside of research protocols.

PCR, a molecular biologic technique that amplifies the signal of small amounts of DNA, is likely to change the future of diagnosis of IAI. Several studies have evaluated amniotic fluid samples using PCR techniques. PCR assay has a higher sensitivity than culture for detection of microorganisms in the amniotic fluid, particularly in patients whose amniotic fluid is culture-negative but other markers indicate evidence of an inflammatory response [59–63].

The term amniotic fluid "sludge" has been proposed to describe "free floating hyperechogenic material within the amniotic fluid in close proximity to the uterine cervix." [64] When aspirated, this "sludge" often resembles pus and may show aggregation of epithelial and white blood cells and bacteria on Gram stain. In one retrospective case-control study, patients with "sludge" had a significantly higher rate of spontaneous preterm delivery; a higher frequency of clinical chorioamnionitis, histologic chorioamnionitis, and funisitis; a higher frequency of preterm PROM; and a shorter median ultrasound-to-delivery interval [65]. The presence of amniotic fluid "sludge" was an independent explanatory variable for the occurrence of spontaneous preterm delivery, preterm PROM, microbial invasion of the amniotic cavity, and histologic chorioamnionitis. In addition, the combination of a cervical length less than 25 mm and "sludge" conferred an OR of 14.8 for spontaneous preterm delivery at less than 28 weeks and an OR of 9.9 for spontaneous preterm delivery at less than 32 weeks.

Rates of IAI are probably underestimated with preterm PROM because severe oligohydramnios may preclude successful sampling. The rate of positive amniotic fluid cultures for microorganisms is higher with preterm PROM (32.4%) than with preterm labor with intact membranes (12.8%) [63]. Additionally, women in labor on hospital admission generally do not have their amniotic fluid sampled, but have been shown to have higher rates of microbial invasion of the amniotic cavity (39%) than women not in labor (25%). When women do enter labor, the risk of microbial invasion of the amniotic cavity is even higher at 75% [66].

### Neonatal Criteria

Most cases of early-onset neonatal sepsis originate in utero. Immediately after delivery, the diagnosis of septicemia is difficult because the neonate's response to infection is impaired, and the reaction is often nonspecific. The earliest signs are often subtle and include changes in color, tone, activity, and feeding patterns; poor temperature control; or simply a general feeling that the neonate is "not doing well." Other possible early signs are abdominal distention, apnea, and jaundice, but they may not appear until later stages, or they may even be seen in healthy premature newborns. Late signs include grunting, dyspnea, cyanosis, arrhythmias, hepatosplenomegaly, petechiae, seizures, bulging fontanelles, and irritability. Focal signs of meningitis or pneumonia may also develop [29].

### Laboratory Criteria in the Placenta and Newborn or Stillborn Infant

Examination of the cord, placenta, or membranes for a leukocytic infiltrate has been suggested as another technique to identify infants at risk for infection. Placental inflammation or funisitis or both are found far in excess of proven cases of sepsis, however, and the technique is cumbersome [7]. In a stillborn with suspected IAI, a blood sample should be obtained to attempt to isolate the infecting microbe. This technique should also be applied in cases of stillbirth with unknown cause.

## CHRONIC INTRA-AMNIOTIC INFECTION

Some evidence suggests that IAI may exist as a chronic condition. Several studies have performed microbiologic studies of mid-trimester genetic amniocentesis fluid. Risk of adverse pregnancy outcome is increased when patients are asymptomatic, but have positive results on such studies at mid-trimester amniocentesis compared with patients with culture-negative fluid [59]. Similarly, amniotic fluid IL-6 concentrations were found to be significantly higher in patients experiencing a loss after mid-trimester amniocentesis than in patients delivering at term [67,68].

Emerging evidence also suggests that chronic inflammation may be present in maternal serum. Goldenberg and colleagues showed elevated granulocyte colony-stimulating factor at 24 weeks and 28 weeks in women subsequently delivering prematurely [69].

Building on the idea that infection could be present before conception, Andrews and associates [70] performed a prospective, randomized trial to evaluate whether interconceptional antibiotics (azithromycin and metronidazole) decreased the rate of preterm birth. In their population of women with a recent early spontaneous birth, administration of these antibiotics did not significantly reduce the rate of subsequent preterm birth. In a subsequent subgroup analysis, this group found that neither baseline endometrial microbial colonization nor plasma cell endometritis was a risk factor for adverse pregnancy outcome. Colonization with specific microbes interacted with the antibiotics to increase adverse outcomes [71]. Interconceptional antibiotics are not recommended at this time in an attempt to reduce subsequent preterm delivery.

## MANAGEMENT

Traditionally, the effectiveness of management of IAI has been viewed in terms of short-term maternal and neonatal outcomes, including maternal sepsis, neonatal sepsis,

pneumonia, meningitis, and perinatal death. This section discusses the management principles of these short-term outcomes.

In the past, there was debate regarding timing of antibiotic administration, but it has now become standard to begin treatment during labor, as soon as possible after the maternal diagnosis of IAI is made. Three studies, including a randomized clinical trial, have shown benefits from intrapartum antibiotic therapy compared with immediate postpartum treatment (Table 3–2) [72–74]. In a large, nonrandomized allocation of intrapartum versus immediate postpartum treatment, the former treatment was associated with a significant decrease in neonatal bacteremia (2.8% versus 19.6%; $P < .001$) and a reduction in neonatal death from sepsis (0.9% versus 4.3%; $P = .07$) [72]. Another large study showed an overall reduction in neonatal sepsis ($P = .06$), especially bacteremia caused by GBS (0% versus 4.7%; $P = .004$), with use of intrapartum treatment [73].

In a randomized clinical trial, Gibbs and associates showed that intrapartum treatment provided maternal benefits (decreased hospital stay, lower mean temperature postpartum) and neonatal benefits (decrease in sepsis [0% versus 21%; $P = .03$] and decreased hospital stay). In this study, neonates received one set of blood cultures and a chest x-ray film. Cerebrospinal fluid specimens were obtained only from infants with referable signs or symptoms. All infants received identical regimens consisting of intravenous ampicillin and gentamicin begun within 1 to 2 hours of birth and continued for at least 72 hours. If bacteremia or neonatal pneumonia was diagnosed, antibiotics were continued for 10 days [74]. Initiation of intrapartum antibiotics leads to a decrease in neonatal death from sepsis and an improved maternal outcome. These benefits seem to outweigh any theoretical arguments (e.g., obscuring positive neonatal cultures) against intrapartum treatment in cases of IAI.

Pharmacokinetic studies [75] done during early pregnancy show that ampicillin concentrations in maternal and fetal sera are comparable 60 to 90 minutes after administration (Fig. 3–2). Penicillin G levels in fetal serum are one third the maternal levels 120 minutes after administration [76]. In addition, ampicillin has some activity against *E. coli*. Ampicillin is preferable to penicillin G for treatment of IAI. When used in combination with an aminoglycoside, ampicillin should be administered first because it has a broader antimicrobial spectrum.

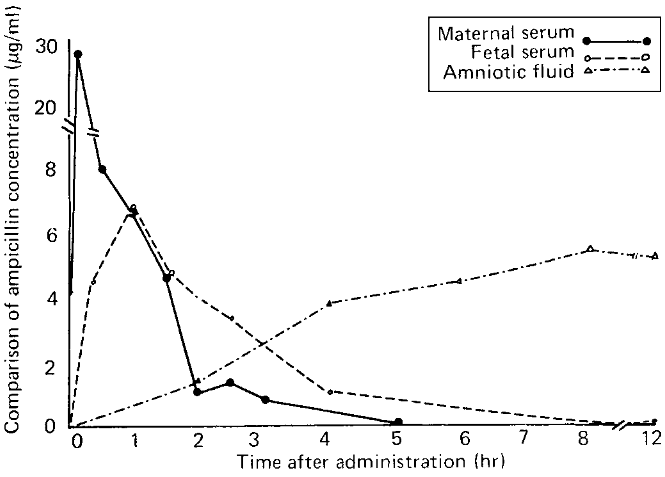

**FIGURE 3–2** Ampicillin levels achieved with systemic administration to the mother. *(From Bray RE, Boe RW, Johnson WL. Transfer of ampicillin into fetus and amniotic fluid from maternal plasma in late pregnancy. Am J Obstet Gynecol 96:938, 1966.)*

In late pregnancy, gentamicin also crosses the placenta rapidly, but peak fetal levels may be low, especially if maternal levels are subtherapeutic [77]. Traditionally, an initial gentamicin dose of at least 1.5 to 2 mg/kg followed by 1 to 1.5 mg/kg every 8 hours is used because of the potential for unfavorable gentamicin kinetics. Locksmith and colleagues [78] evaluated maternal and fetal serum drug levels between women who received the standard gentamicin dosing versus once-daily dosing (5 mg/kg every 24 hours). The authors found that the once-daily dosing regimen resulted in fetal serum peak levels that were closer to optimal neonatal values. No adverse effects of once-daily dosing were seen. Achieving the same gentamicin levels in the fetus as are targeted in the newborn infant seems worthy of future investigation.

Clindamycin achieves peak concentrations in maternal blood within minutes after injection and in fetal blood shortly thereafter. In pharmacokinetic studies later in pregnancy, peak clindamycin concentrations were approximately one half of maternal peaks, but the former were still within therapeutic ranges [77].

**TABLE 3–2** Comparative Studies of Intrapartum versus Postpartum Maternal Antibiotic Therapy in Treatment of Intra-amniotic Infection

| Author, Year | Design/Setting | No. Patients | Maternal Intrapartum Antibiotic Regimen | Benefits of Intrapartum Treatment |
|---|---|---|---|---|
| Sperling et al [28], 1987 | Retrospective/public teaching hospital in San Antonio, TX | 257 | Penicillin G plus gentamicin IV | NNS reduced from 19.6% in postpartum treatment group to 2.8% in intrapartum treatment group ($P = .001$) |
| Gilstrap et al, 1988 | Retrospective/public teaching hospital in Dallas, TX | 273 | Varied* | NNS reduced from 5.7% in postpartum treatment group to 1.5% in intrapartum treatment group ($P = .06$); group B streptococcal bacteria reduced from 5.7% to 0% ($P = .004$) |
| Gibbs et al, 1988 | Randomized clinical trial/same as Sperling (1987) | 45 | Ampicillin plus gentamicin IV | NNS reduced from 21% to 0%; maternal morbidity also decreased ($P = .05$) |

**Antibiotic regimens noted as 47% received ampicillin or penicillin in combination with gentamicin and clindamycin; 22%, ampicillin or penicillin with gentamicin; 20%, cefoxitin; and 11%, other antibiotics.*

*IV, intravenously; NNS, neonatal sepsis confirmed by blood culture.*

As an alternative, a newer penicillin or cephalosporin with excellent activity against aerobic gram-negative bacteria might be used. There is little published experience with these other antibiotics in IAI, however. In cases of clinical chorioamnionitis, one study showed that clindamycin, mezlocillin, ampicillin, cefoxitin, and gentamicin all penetrated into cord blood and placental membranes, with achievement of therapeutic concentrations in cord blood [79].

The traditional antibiotic choice in cases of IAI includes a combination of a broad-spectrum penicillin with an aminoglycoside, plus clindamycin in some cases (e.g., cesarean delivery or apparent sepsis). Because of expense and complexity, there has been interest in treatment of IAI with a single agent. In view of the typical causative microbes, there are several reasonable choices for single-drug treatment, such as extended-spectrum penicillin (piperacillin, tazobactam) or extended-spectrum cephalosporins (cefotetan). More recent studies have addressed the issue of duration of antibiotic therapy postpartum in cases of IAI. One randomized trial compared single-dose versus multidose postpartum treatment of mothers and reported that single-dose treatment was accompanied by a shorter time to discharge (33 hours versus 57 hours; $P = .001$) [80]. The single-dose group had a nearly threefold increase in failure of therapy, but this did not achieve statistical significance (11% versus 3.7%; $P = .27$). Although not statistically significant, this threefold increase in "failed therapy" elicits concern regarding single-dose postpartum therapy for IAI.

In a study of antibiotic therapy after cesarean delivery for chorioamnionitis, Turnquest and associates [29] randomly assigned patients to receive no scheduled postoperative antibiotics or clindamycin and gentamicin until they were afebrile (for a minimum of at least 24 hours.) All patients received ampicillin in labor, and clindamycin and gentamicin, one dose each preoperatively. No patients in either group developed an abscess or were readmitted for endometritis. Although there was no significant difference in endometritis (14.8% in patients with no routine antibiotic versus 21.8% in patients who received clindamycin and gentamicin), there was a 2.5-fold increase in wound infection rate in patients who did not receive scheduled postpartum antibiotics (5% versus 1.8%).

A subsequent study randomly assigned postpartum patients with chorioamnionitis to receive ampicillin (2 g every 6 hours) and gentamicin (1.5 mg/kg every 8 hours) until afebrile and asymptomatic for 24 hours (control group) or to receive only the next scheduled dose of each antibiotic [81]. In this study, 40% of patients delivered by cesarean section. All patients received ampicillin and gentamicin intrapartum; patients who underwent cesarean delivery also received clindamycin (900 mg) at cord clamping. Patients in the control group had clindamycin continued every 8 hours until antibiotics were discontinued, whereas patients in the study group received only the one dose of clindamycin. The primary outcome was failure of treatment, defined as one temperature elevation after the first postpartum antibiotics dose of 39° C or more than two temperatures of 38.4° C, at least 4 hours apart. These two regimens had similar rates of failure. Based on the information related here, it seems that when antibiotic treatment is initiated early, a short course of therapy in the puerperium is sufficient therapy in most patients.

## SHORT-TERM OUTCOMES

With regard to timing of delivery, short-term outcome does not depend on duration of chorioamnionitis [2,82–85]. Cesarean delivery usually is reserved for standard obstetric indications, not for IAI itself. No critical interval from diagnosis of amnionitis to delivery could be identified. Specifically, neither prenatal mortality nor maternal complications correlated with more prolonged intervals from diagnosis of chorioamnionitis to delivery, yet all patients delivered within 4 to 12 hours. Nearly all of these cases described pregnancy at or near term, however. Rates of cesarean section are two to three times higher among patients with IAI than in the general population, owing to patient selection (most cases occur in women with dystocia already diagnosed) and a poor response to oxytocin [86,87].

We use a combination of an intravenous penicillin and intravenous gentamicin as soon as the diagnosis of IAI is made [2,88]. Several studies have reported good results with similar regimens [82]. When a cesarean section is necessary, clindamycin should be added postpartum to these antibiotics to cover anaerobic microbes that are associated with post–cesarean section infection and because of high failure rate (20%) with penicillin and gentamicin therapy after cesarean section [1]. Other initial regimens with cefoxitin alone or ampicillin plus a newer cephalosporin may be equally effective, but no comparative trials have been performed.

Since 1979, retrospective studies have shown a vastly improved perinatal outcome compared with perinatal outcomes reported in older studies. Gibbs and colleagues reported a retrospective study of 171 patients with IAI in whom therapy (with penicillin G and kanamycin) usually was begun at the time of diagnosis [1]. The mean gestational age of the neonate was 37.7 weeks. There were no maternal deaths, and bacteremia was found in only 2.3% of mothers. Among women with IAI, the rate of cesarean delivery was increased approximately threefold to 35%, mainly because of dystocia. The outcome was good in all mothers. There was only one episode of septic shock, with no pelvic abscesses or maternal deaths. Similar results were reported from Los Angeles County Hospital [89].

Gibbs and colleagues found that when IAI is present, perinatal mortality rate (140 per 1000 births) was approximately seven times the overall perinatal mortality rate for infants weighing more that 499 g (which was 18.2 per 1000 births) [1]. None of the perinatal deaths was clearly attributable to infection, however; of live-born infants weighing more than 1000 g, none died of infection. In the study by Koh and coworkers, the perinatal mortality rate was lower (28.1 per 1000 births), which probably reflected the higher mean gestational age (39.3 weeks) [89]. There were no intrapartum fetal deaths and only four neonatal deaths. No deaths were due to infection. Neither perinatal nor maternal complications correlated with more prolonged diagnosis-to-delivery intervals. Because patients who underwent cesarean section had more complicated courses, it was concluded that cesarean section should be reserved for patients with standard obstetric indications.

Yoder and colleagues later reported a prospective, case-control study of 67 neonates with microbiologically confirmed IAI at term [88]. There was only one perinatal

death, which was unrelated to infection. Cerebrospinal fluid culture results were negative for all 49 infants tested, and there was no clinical evidence of meningitis. Findings on chest radiographs were interpreted as possible pneumonia in 20% of patients and as unequivocal pneumonia in only 4%. Neonatal bacteremia was documented in 8%. There was no significant difference in the frequency of low Apgar scores between the IAI and control groups.

Two other retrospective studies have been confirmatory. Looff and Hager reported the outcomes of 104 pregnancies with clinical chorioamnionitis [82]. The mean gestational age was 36 weeks. The perinatal mortality rate was 123 per 1000 births. Nearly all of the excess mortality was attributed to prematurity, rather than to sepsis. These authors also reported an increase in the cesarean delivery rate. Hauth and coworkers reviewed data for 103 pregnancies with clinical chorioamnionitis at term [83]. The mean interval from diagnosis of amnionitis to delivery was 3.1 hours, which confirmed the absence of a critical interval for delivery. In this study, the overall perinatal mortality rate was 9.7 per 1000 births, and the cesarean delivery rate was 42%.

Neonates born prematurely have a higher frequency of complications if their mothers have IAI. Garite and Freeman noted that the perinatal death rate was significantly higher in 47 preterm neonates with IAI than in 204 neonates with similar birth weights, but without IAI [90]. The group with IAI also had a significantly higher percentage (13% versus 3%; $P < .05$) with RDS and total infection. A larger but similar comparative study of 92 patients with chorioamnionitis and 606 controls of similar gestational age also showed significant increases in mortality, RDS, intraventricular hemorrhage (IVH), and clinically diagnosed sepsis in the group with chorioamnionitis (Table 3–3) [91]. When Sperling and associates stratified outcomes in cases of IAI by birth weight, cases with low birth weight were associated with more frequent maternal bacteremia (13.5% versus 4.9%; $P = .06$), early-onset neonatal sepsis (16.2% versus 4.1%; $P = .005$), and neonatal death from sepsis (10.8% versus 0; $P < .001$) [92].

In a retrospective, case-control study, Ferguson and coworkers reported neonatal outcome after chorioamnionitis [93]. Of newborns, 70% weighed less than 2500 g. In 116 matched pairs, the authors found more deaths (20% versus 11%), more sepsis (7% versus 2%), and more asphyxia (27% versus 16%) in the group with chorioamnionitis. None of these differences, achieved statistical significance.

Chorioamnionitis has been previously considered a maternal infection. Increasing evidence indicates, however, that the fetus is primarily involved in the inflammatory response leading to premature delivery. Fetal inflammatory response syndrome, well described by Yoon and colleagues, characterizes preterm PROM and spontaneous preterm labor, with a systemic proinflammatory cytokine response resulting in earlier delivery and with an increased risk of complications [94]. Additionally, these investigators showed an association between the fetal inflammatory cascade and fetal white matter damage [95]. It is unclear, however, whether cytokines mediate this damage or directly cause the damage, or whether infection itself is responsible for the damage. Cytokines also can be stimulated by many noninfectious insults, such as hypoxia, reperfusion injury, and toxins [96].

IAI has a significant adverse effect on the mother and neonate. Outcome largely depends on the involved microbes (with *E. coli* and GBS more likely to result in maternal or neonatal bacteremia), birth weight (with low birth weight infants faring more poorly), and timing of antibiotic therapy (with intrapartum administration improving outcome.)

## LONG-TERM OUTCOME

Hardt and colleagues studied long-term outcomes in preterm infants (weighing <2000 g) born after a pregnancy with chorioamnionitis and found a significantly lower mental development index (Bayley score) for the infants than seen in preterm control infants (104 ± 18 versus 112 ± 14; $P = .017$) [97]. Morales reported 1-year follow-up of preterm infants born after pregnancy with chorioamnionitis and of control infants. Differences in mental and physical development were not observed, but adjustments were made for IVH and RDS, both of which were more frequent in the amnionitis group [91].

Intriguing new information strongly suggests that intrauterine exposure to bacteria is associated with long-term serious neonatal complications, including cerebral palsy or its histologic precursor, periventricular leukomalacia (PVL), and major pulmonary problems of bronchopulmonary dysplasia and RDS. The unifying hypothesis states that intrauterine exposure of the fetus to infection leads to abnormal fetal production of proinflammatory cytokines; this leads to fetal cellular damage in the brain, lung, and, potentially, other organs. This fetal inflammatory response syndrome has been likened to systemic inflammatory response syndrome in adults. The evidence linking infection to cerebral palsy may be summarized as follows:

1. Intrauterine exposure to maternal or placental infection is associated with an increased risk of cerebral palsy in preterm and term infants [98–101].

**TABLE 3–3** Perinatal Outcome in Preterm Amnionitis (Intra-amniotic Infection)

| | Amnionitis* | | Control* | |

*At centers reporting these results, there were active referral services. In these series of consecutive patients with preterm premature rupture of membranes, patients with amnionitis are compared with patients without amnionitis.*

†*Rates are significantly lower than for amnionitis group in corresponding study.*

*NR, not reported.*

2. Clinical chorioamnionitis in infants with very low birth weight is significantly associated with an increase in PVL ($P = .001$) [102].
3. The levels of inflammatory cytokines are increased in the amniotic fluid of infants with white matter lesions (PVL), and there is overexpression of these cytokines in neonatal brain with PVL [103].
4. Experimental intrauterine infection in animal models leads to brain white matter lesions [104,105].
5. Marked inflammation of the fetal side of the placenta is associated with adverse neurologic outcomes. Coexisting evidence of infection and thrombosis, particularly on the fetal side of the placenta, is associated with a heightened risk of cerebral palsy or neurologic impairment in term and preterm infants. Additionally, histologic funisitis is associated with an increased risk of subsequent cerebral palsy (OR 5.5, 95% confidence interval [CI] 1.2 to 24.5) [102,106–108]. This risk underscores the importance of sending placentas to pathology for gross and microscopic examination in the setting of IAI.

The association between IAI and cerebral palsy differs for term and preterm infants. A review article outlined the controversies in this area, including the associations among microbiologic, clinical, and histologic chorioamnionitis [109]. Additionally, emerging evidence points to genetic predispositions to inflammation and thrombosis. Cytokine polymorphisms also may be linked to cerebral palsy [96].

In addition to cellular and tissue damage in the fetal brain, an overexuberant cytokine response induced by bacteria may damage other fetal tissues, such as the lung, contributing to RDS and bronchopulmonary dysplasia [110]. In support of this hypothesis, a case-control study of infants with and without RDS was conducted. Infants with RDS were significantly more likely to have elevated levels of amniotic fluid tumor necrosis factor (TNF)-α, a positive culture of the amniotic fluid, and severe histologic chorioamnionitis ($P < .05$ for each association). Elevated amniotic fluid IL-6 levels were also twice as common in the group with RDS, but this association did not achieve statistical significance. Preterm fetuses with elevated cord blood IL-6 concentrations (>11 pg/mL) were more likely to develop RDS (64% versus 24%; $P < .005$) than preterm fetuses without elevated cord IL-6 levels. Rates of occurrence of bronchopulmonary dysplasia also were increased (11% versus 5%), but the observed difference was not statistically significant [111]. Curley and associates found elevated matrix metalloproteinase (MMP)-9 concentration in bronchoalveolar lavage fluid in preterm neonates with pregnancies complicated by chorioamnionitis compared with age-matched uninfected controls. These investigators hypothesized that increased MMP levels in the lung cause destruction of the extracellular matrix, breaking down type IV collagen in the basement membrane and leading to the failure of alveolarization and to the fibrosis components of chronic lung disease [112].

More recently, genetic predisposition toward exuberant host response to tissue injury has been described. Proinflammatory cytokine polymorphisms such as TNF-α 308 relate to bacterial endotoxin and an increased risk of preterm delivery [113–115].

IAI has significant adverse effects on the mother and neonate, but vigorous antibiotic therapy and reasonable prompt delivery result in an excellent short-term prognosis, especially for the mother and term neonate. With the combination of prematurity and amnionitis, serious sequelae are more likely for the neonate. Newer information suggests that intrauterine infection is linked to major neonatal long-term complications. A complex interplay of cytokine genotypes may contribute to long-term complications as well.

**TABLE 3–4** Proposed Prevention Strategies for Clinical Intra-amniotic Infection

| |
|---|
| Prompt management of dystocia |
| Induction of labor with premature rupture of membranes at term |
| Antibiotic prophylaxis with preterm premature rupture of membranes |
| Antibiotic prophylaxis with preterm labor, but with intact membranes |
| Antibiotic prophylaxis for group B streptococcal infection |
| Prenatal treatment of bacterial vaginosis |
| Chlorhexidine vaginal irrigations in labor |
| Infection control measures |

## CONCLUSION

The unanswered question remains: Why does IAI develop in some patients and not in others? Investigations of maternal and fetal genotypes for proinflammatory markers, among others, and study of mucosal immunity and host response may help to answer this important question and clarify when neonatal damage occurs. Satisfactory therapeutic approaches cannot be developed until we understand the answers to these questions.

### Prevention

As categorized in Table 3–4, numerous approaches have been proposed for the prevention of IAI. Among these, prompt management of dystocia has been shown to decrease chorioamnionitis and to shorten labor and reduce cesarean section rate [5]. Similarly, induction in women with PROM at term most likely results in fewer maternal infections than may occur with expectant management [115]. Antibiotic prophylaxis for patients with preterm PROM decreases chorioamnionitis and other complications [116,117]. Treatment for bacterial vaginosis in high-risk women decreases the incidence of preterm birth. Antibiotic prophylaxis for patients in preterm labor (but with intact membranes) does not seem to decrease frequency of chorioamnionitis [118]. Intrapartum prophylaxis for the prevention of neonatal sepsis with GBS is now a national standard in patients with GBS colonization or in patients with specific high risks. It is presumed that this approach also decreases chorioamnionitis, but there are no definitive data to support this. Prenatal treatment of bacterial vaginosis in low-risk women, chlorhexidine vaginal washes in labor, and specific infection control measures have not been shown to be effective [22,119–122].

## INFECTION AS A CAUSE OF PRETERM BIRTH

Preterm birth is a leading perinatal problem in the United States, and rates continue to increase. In 2005, the rate of preterm birth before 37 completed weeks of gestation

**TABLE 3–5** Evidence for Relationship between Preterm Births and Subclinical Genitourinary Tract Infection

| |

| Infection and inflammation cause cytokine release and prostaglandin production |
| Bacteria and bacterial products induce preterm delivery in animal models |
| Amniotic fluid tests for bacteria are positive in some patients in premature labor |
| Some antibiotic trials have shown a decrease in numbers of preterm births |

increased to 12.7%, an increase of 20% since 1990 and 9% since 2000 [123]. Preterm infants account for 70% of all perinatal deaths and half of long-term neurologic morbidity.

In most cases, the underlying cause of premature labor is not evident. Evidence from many sources points to a relationship between preterm birth and genitourinary tract infections (Table 3–5) [124,125]. In addition to the genitourinary tract, infection leading to preterm birth may arise in a more remote site, such as the lung or periodontal tissues [126–129]. Newer information has suggested that subclinical infection is responsible not only for preterm birth, but also for many serious neonatal sequelae, including PVL, cerebral palsy, RDS, bronchopulmonary dysplasia, and necrotizing enterocolitis [96,98–110].

## HISTOLOGIC CHORIOAMNIONITIS AND PREMATURITY

Over the past 3 decades, one of the most consistent observations is that placentas in premature births are more likely to show evidence of inflammation (i.e., histologic chorioamnionitis) (Fig. 3–3). In a series of 3500 consecutive placentas, Driscoll found infiltrates of polymorphonuclear cells in 11% [130]. Clinically evident infection developed in only a few of the women in the study, but the likelihood of neonatal sepsis and death was increased [131].

An association has been established between histologic chorioamnionitis and chorioamnion infection (defined as a positive culture) [131]. ORs of 2.8 to 14 have been reported, this relationship being stronger among preterm deliveries than among term deliveries. Overall, the organisms found in the chorioamnion are similar to organisms found in the amniotic fluid in cases of clinical IAI. This array of organisms supports an ascending route for chorioamnion infection in most cases.

Although it is uncertain how histologic chorioamnionitis and membrane infection cause preterm delivery or preterm PROM, studies suggest that they lead to weakening of the membranes (as evidenced by lower bursting tension, less work to rupture, and less elasticity [132] in vitro) and to production of prostaglandins by the amnion [133,134].

The rate of histologic chorioamnionitis increases with decreasing gestational age at delivery. In one study, when birth weight was greater than 3000 g, the percentage of placentas showing histologic chorioamnionitis was less than 20%; when birth weight was less than 1500 g, the percentage was 60% to 70% [135].

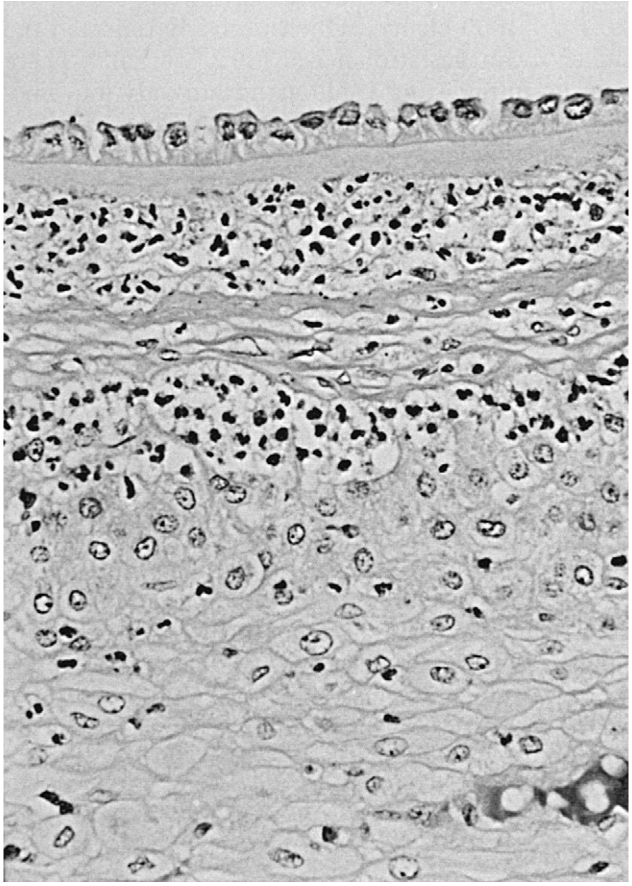

**FIGURE 3–3** Infiltrates of polymorphonuclear cells are seen in fetal membranes. Inflammation of placenta and membranes has been consistently observed more often after preterm births than after term births.

## CLINICAL INFECTION AND PREMATURITY

Premature infants and women who previously gave birth to premature infants are more likely to develop clinically evident infection [136]. In a large study of more than 9500 deliveries, confirmatory evidence showed that chorioamnionitis, endometritis, and neonatal infection all were significantly increased in preterm pregnancies, even after correcting for the presence of PROM [137]. These observations suggest that subclinical infection led to the labor and that infection became clinically evident after delivery. Some investigators argue that there is no causal relationship, but that infection develops more frequently in premature infants because they are compromised hosts, or because they have more invasive monitoring in the nursery.

Strong evidence supports the relationship between preterm birth and genitourinary tract infections. Untreated bacteriuria in pregnancy leads to acute pyelonephritis in 20% to 40% of patients; pyelonephritis has a significantly increased risk of fetal morbidity and mortality. Untreated acute pyelonephritis is associated with a 30% risk of preterm labor and delivery. A meta-analysis [138] showed that women with asymptomatic bacteriuria had a 60% higher rate of low birth weight (95% CI 1.4 to 1.0) and a 90% higher rate of preterm delivery (95% CI 1.3 to 1.9).

Mounting evidence indicates that periodontal disease is associated with preterm birth. A meta-analysis [139] stated that a "likely association" existed between periodontitis and preterm birth or low birth weight, with approximately a twofold increased risk for preterm birth in patients with periodontal disease. As Stamilio and colleagues pointed out [140], the validity of the meta-analytic results is limited by the quality of studies that comprise the analysis. In addition, association does not always correspond to causation. Finally, we can never conclude that an association leads to proof of efficacy for an intervention. Based on all of the available information, the authors do not recommend dental interventions as preventive therapy for preterm birth.

## ASSOCIATION OF LOWER GENITAL TRACT ORGANISMS OR INFECTIONS WITH PREMATURITY

Premature birth has been associated with isolation of several organisms from the maternal lower genital tract and with subclinical infections, as listed in Table 3–6. A large collaborative study including more than 4500 patients showed that lower genital tract colonization with *U. urealyticum* is not associated with preterm birth; this organism is one of the most commonly isolated in the amniotic fluid of women in preterm labor. Similarly, cervical infection with *C. trachomatis* is not associated with preterm birth [141].

Other lower genital tract or urinary infections, including infections caused by *N. gonorrhoeae* and *Trichomonas vaginalis* and bacteriuria, are associated with preterm birth, however. Several studies found increased OR for preterm birth among women with *T. vaginalis* infection [125]. In the large Vaginal Infections and Prematurity Study, lower genital tract carriage of *T. vaginalis* at mid-pregnancy was significantly associated with preterm low birth weight. Preterm low birth weight occurred in 7.1% of women with *T. vaginalis* compared with 4.5% of women without *T. vaginalis* (OR 1.6, 95% CI 1.3-1.9) [142]. Bacterial vaginosis, characterized by high concentrations of anaerobes, *G. vaginalis*, and genital mycoplasmas, with a corresponding decrease in the normal vaginal lactobacilli, confers an approximately twofold to threefold increase in spontaneous premature birth. It is unclear whether bacterial vaginosis causes preterm delivery by leading to subclinical infection, or whether bacterial vaginosis acts locally in the lower genital tract infections because it is associated with increased concentrations of elastase, mucinase, and sialidase (hydrolytic enzymes associated with increased risks of adverse pregnancy outcomes) [143–148].

Macones and colleagues presented evidence that an interaction between genetic susceptibility and environmental factors (i.e., bacterial vaginosis) increased the risk of spontaneous preterm birth. Specifically, they showed that maternal carriers of TNF-2 were at significantly increased risk of spontaneous preterm birth (OR 2.7, 95% CI 1.7-4.5). The association between TNF-2 and preterm birth was modified by the presence of bacterial vaginosis; mothers with a "susceptible" genotype and bacterial vaginosis had an increased OR of preterm birth compared with mothers who did not (OR 6.1, 95% CI 1.9-21.0) [149].

Maternal genital tract colonization with GBS may lead to neonatal sepsis, especially when birth occurs prematurely, or when the membranes have been ruptured for prolonged intervals. In addition, Regan and coworkers [150] found an association between colonization of the cervix with these organisms and premature birth. These investigators noted delivery at less than 32 weeks in 1.8% of the total population, but in 5.4% of women colonized with GBS ($P < .005$). PROM also occurred significantly more often in the colonized group (15.3% versus 8.1%; $P < .005$). Of six studies evaluating the association between GBS genital colonization and preterm labor or delivery, five found no association [125].

In contrast with the conflicting data regarding genital colonization with GBS, GBS bacteriuria has been consistently associated with preterm delivery, and treatment of this bacteriuria resulted in a marked reduction in prematurity (37.5% in the placebo group versus 5.4% in the treatment group) [151–153]. In a randomized treatment trial of erythromycin versus placebo in women colonized with GBS, erythromycin use was not shown to be effective in prolonging gestation or increasing birth weight [154].

Current recommendations for prevention of perinatal infection with GBS from the U.S. Centers for Disease Control and Prevention (CDC) are for intrapartum treatment only, with the exception of GBS bacteriuria, which should be treated antepartum. The 2002 CDC guidelines recommend adoption of universal screening. The universal screening approach involves screening women at 35 to 37 weeks of gestation with proper collection and culture techniques, followed by intrapartum treatment for all women with positive cultures [155].

**TABLE 3–6** Association of Lower Genitourinary Tract Infections with Preterm Birth

| Infection | Odds Ratio for Preterm Birth (95% Confidence Interval) |
|---|---|
| *Ureaplasma urealyticum* | 1.0 (0.8-1.2)[a] |
| *Chlamydia trachomatis* | 0.7 (0.36-1.37)[b,c] |
| *Neisseria gonorrhoeae* | 531 (1.57-17.9)[d] |
| *Trichomonas vaginalis* | 1.3 (1.1-1.4)[e] |
| Bacterial vaginosis | 1.3 (1.1-1.4)[f] |

## AMNIOTIC FLUID CULTURES IN PRETERM LABOR

Among patients with signs and symptoms of preterm labor, the probability of finding a positive result on tests for bacteria depends on several factors: the specimen tested, the

population under investigation, and the technique used for microbial detection. When standard culture techniques have been used for the amniotic fluid of patients clinically defined as being in preterm labor, the likelihood of positive cultures ranges from 0% to 25%. Yet with culture of the amniotic fluid of patients in preterm labor who deliver a preterm infant within 72 hours of the amniocentesis, the likelihood of a positive result has been 22%. With use of more sensitive assays such as PCR, the probability of finding bacteria in the amniotic fluid of patients in preterm labor has been 30% to 55% [60–62,125,156]. Because bacteria are likely to be present in the amniotic membranes before appearing in the amniotic fluid, the rate of positive cultures of the membranes for patients in preterm labor has been 32% to 61%. Histologic evidence of chorioamnion infection is extremely common, being found in approximately 80% of placentas after birth of infants weighing 1000 g or less.

## BIOCHEMICAL LINKS OF PREMATURITY AND INFECTION

The widely accepted working hypothesis is that bacteria ascending into the uterine cavity are able to stimulate cytokine activity directly. IL-1, IL-6, and TNF-α, the proinflammatory cytokines, have been shown to be produced by the fetal membranes, decidua, and myometrium. Patients with elevated levels of these cytokines in the amniotic fluid have shorter amniocentesis-to-delivery intervals than patients without elevated cytokine levels. Levels also are elevated when preterm labor is associated with IAI [156]. Similarly, Gomez and associates [157] showed that elevated fetal plasma levels of IL-6 in patients with preterm PROM, but not in labor, had a higher rate of delivery within 48 hours compared with patients who delivered more than 48 hours after cordocentesis. These important findings suggest that a fetal inflammatory cytokine response triggers spontaneous preterm delivery.

Immunomodulatory cytokines, such as IL-1 receptor antagonist (IL-1ra), IL-10, and transforming growth factor (TGF)-β, play a regulatory role in the cytokine response, allowing for a downregulation of this response [158]. IL-1ra has been shown in humans to increase in response to IAI [159]. Murtha and coworkers showed that maternal carriage of at least one copy of the IL-1ra allele 2 is associated with increased risk of preterm birth [159]. Similarly, Mulherin and colleagues reported that common genetic variants in proinflammatory cytokine genes could influence the risk for spontaneous preterm birth. They found that selected TNF-α haplotypes were associated with spontaneous preterm birth in African American and white subjects [160]. IL-10 inhibits IL-1β–induced preterm labor in a rhesus model [161].

Animal models have been used to evaluate cytokine-mediated initiation of preterm birth. Romero and colleagues showed that systemic administration of IL-1 induced preterm birth in a murine model [162]. Similarly, Kaga and coworkers gave low-dose lipopolysaccharide intraperitoneally to preterm mice, causing preterm delivery [163]. Again using a murine model, other investigators showed preterm birth after intrauterine inoculation of *E. coli*.

Other investigators have used inoculation of live bacteria to study the infection-cytokine-preterm birth pathway. In rabbits, we found that intrauterine inoculation of *E. coli*, *Fusobacterium* species, or GBS led to rapid induction of labor at 70% gestation with an accompanying increase in histologic infiltrate and elaboration of TNF-α into the amniotic fluid. More recently, using our rabbit model, we showed that intrauterine inoculation of the anaerobe *Prevotella bivia* at 70% gestation led to establishment of a “chronic” infection in 64% of animals, with preterm birth occurring in 33% [164]. Also, using a rhesus monkey model, Gravett and colleagues inoculated GBS at 78% gestation and found resulting increases in amniotic fluid cytokines and prostaglandins followed by a progressive cervical dilation [165].

## ANTIBIOTIC TRIALS

Antibiotic treatment trials may be categorized into three general types as follows: (1) antibiotics given during prenatal care to patients at increased risk of preterm delivery; (2) antibiotics given adjunctively with tocolytics to women in preterm labor; and (3) antibiotics given to women with preterm PROM, but not yet in labor. In the prototype of the first category of antibiotic trial, Kass and colleagues [166] and McCormack and associates [167] noted a reduction in the percentage of low birth weight infants delivered of women who received oral erythromycin for 6 weeks in the third trimester compared with infants delivered of women who were given a placebo. These results were not confirmed in a National Institutes of Health–sponsored, multi-institutional study. More than 1100 women with genital *U. urealyticum* were randomly assigned to receive placebo or erythromycin beginning at 26 to 28 weeks of gestation and continuing until 35 weeks. No improvement was detected in any outcome measure, including no difference in birth weight, low birth weight, or prematurity rate (Table 3–7). Treatment of *U. urealyticum* in pregnancy to prevent prematurity remains experimental.

Two retrospective, nonrandomized studies have reported reductions in PROM, low birth weight, and preterm labor through antenatal treatment of *C. trachomatis* infection [168, 169]. In the first study, patients successfully treated for *C. trachomatis* had significantly lower rates of PROM and premature labor than patients who failed to have *C. trachomatis* eradicated. In the second study, adverse outcome was assessed among three large groups: *C. trachomatis*–positive

but untreated ($n = 1110$), *C. trachomatis*–positive and treated ($n = 1327$), and *C. trachomatis*–negative ($n = 9111$). The *C. trachomatis*–positive but untreated group had PROM and low birth weight significantly more often and had higher perinatal mortality than the other two groups. The only randomized treatment trial for *C. trachomatis* in pregnancy led to conflicting results, however [170]. In this latter study, the rate of pregnancies resulting in low birth weight infants was reduced in three of the five centers, but not significantly reduced in the remaining two. A more recent study by the NICHD Maternal-Fetal Medicine Units Network found that treatment of *C. trachomatis* in the midtrimester was not associated with a decreased frequency of preterm birth [141]. At the present time, it is standard of care to treat women with *C. trachomatis* infection, not as much to prevent preterm labor, but to prevent spread of the sexually transmitted disease.

Treatment with metronidazole should be offered to women who have symptomatic *T. vaginalis* infection in pregnancy to relieve maternal symptoms and prevent spread of a sexually transmitted disease [171]. Metronidazole is safe for use in the first trimester of pregnancy [172]. When pregnant women with asymptomatic *T. vaginalis* infection at 24 to 29 weeks of gestation were randomly assigned to receive treatment with either metronidazole or placebo, rates of delivery at less than 37 weeks and at less than 37 weeks because of preterm labor were increased in the group given metronidazole (relative risk 1.8 [95% CI 1.2 to 2.7] for delivery at <37 weeks and relative risk 3.0 [95% CI 1.5 to 5.9] for delivery at <37 weeks because of preterm labor) [173].

Because of the consistent association of bacterial vaginosis with preterm birth, several treatment trials have been carried out in pregnant women. A meta-analysis reported no significant reduction in preterm delivery when women with bacterial vaginosis were given antibiotic therapy as part of prenatal care. Similarly, there is no significant reduction in preterm labor with treatment for bacterial vaginosis in women at low risk for preterm birth. In the subset of women with previous preterm birth and treatment for at least 7 days with an oral regimen, there was a significant reduction in preterm delivery (OR 0.42, 95% CI 0.27 to 0.67). Following the meta-analysis, the PREMET study [174], a randomized controlled trial, concluded that oral metronidazole does not reduce early preterm birth in high-risk women (selected by history and a positive vaginal fetal fibronectin test). Whether vaginal treatment of bacterial vaginosis is effective in preventing preterm birth is unclear. In the meta-analysis, no benefit was obtained by vaginal treatment [175]. Subsequent trials supported the idea, however, that a course of clindamycin cream early in pregnancy leads to a decreased incidence of preterm birth [176,177].

Among women in preterm labor with intact membranes, there have been several studies and meta-analyses studying the effect of various antibiotic regimens. The ORACLE II study showed no delay in delivery or no improvement in a composite outcome that included neonatal death, chronic lung disease, or cerebral anomaly [178]. In the Cochrane meta-analysis, 7428 women in 11 trials were assessed. As shown in Table 3–8, the use of antibiotics did not decrease preterm birth delivery within 48 hours or perinatal mortality. The relative risk for neonatal death in the antibiotic treatment group was 1.52 (95% CI 0.99 to 2.34). There was a significant reduction in postpartum intrauterine infection with use of antibiotics, but this reduction was not seen as sufficient justification for widespread use of antibiotics in preterm labor.

**TABLE 3–8** Risk of Selected Adverse Outcomes with Use of Antibiotics in Preterm Labor with Intact Membranes

| Outcome | RR* (95% Confidence Interval) |
|---|---|
| Preterm birth | 0.99 (0.92-1.05) |
| Delivery within 48 hr | 1.04 (0.89-1.23) |
| Perinatal mortality | 1.22 (0.88-1.70) |
| Neonatal death | 1.52 (0.99-2.34) |

**Relative risk (RR) <1.0 favors antibiotics, and RR >1.0 favors controls. RR is statistically significant if the 95% confidence interval excludes 1.0.*
*From King J, Flenady V. Prophylactic antibiotics for inhibiting preterm labour with intact membranes. Cochrane Database Syst Rev (1), 2003.*

In a subanalysis, the reviewers looked at trials employing antibiotics that were active against anaerobes (i.e., metronidazole or clindamycin). There were significant benefits in delivery within 7 days and in neonatal intensive care unit admissions. These benefits were not accompanied, however, by significant reductions in major end points such as preterm birth, perinatal mortality, or neonatal sepsis.

There have been several large trials among patients with preterm PROM. In 2003, the Cochrane Library updated its meta-analysis of these trials. In 13 trials comprising 6000 patients, antibiotics in this clinical setting had consistent benefits. Among women given antibiotics, delivery within 48 hours, delivery within 7 days, or development of chorioamnionitis was less likely. Their neonates were less likely to have infection or sepsis (Table 3–9).

Lack of consistent findings in these antibiotic trials raises the question of why antibiotics have been effective in so few clinical situations. One likely explanation is that a true effective antibiotic may be "diluted out" by inclusion in the trials of patients in whom premature labor is not due to infection, such as patients in preterm labor at 34 to 37 weeks. Another likely explanation is that when clinical signs and symptoms of preterm labor begin, the complex biochemical reactions have progressed too far to be stopped by antibiotic therapy alone.

Widespread use of antibiotics for the purpose of prolonging a premature pregnancy raises concerns

**TABLE 3–9** Risk of Selected Adverse Outcomes with Use of Antibiotics for Preterm Premature Rupture of Membranes

| Outcome | RR* (95% Confidence Interval) |
|---|---|
| Delivery within 48 hr | 0.71 (0.58-0.87) |
| Delivery within 7 days | 0.8 (0.71-0.9) |
| Chorioamnionitis | 0.57 (0.37-0.86) |

**TABLE 3–10** Consensus on Use of Antibiotics to Prevent Preterm Birth

| Opinion | Comment |
|---|---|
| ***During Prenatal Care*** | |
| Treat *Neisseria gonorrhoeae* and *Chlamydia trachomatis* infection | Screening and treatment of these two sexually transmitted organisms should follow standard recommendations to prevent spread to sexual partner(s) and the newborn. Published nonrandomized trials show improved pregnancy outcome with treatment. |
| Treat bacteriuria, including group B streptococcal bacteriuria | Screening and treatment for bacteriuria is a standard practice to prevent pyelonephritis. A meta-analysis concluded that bacteriuria is directly associated with preterm birth. |
| Screen for and treat bacterial vaginosis in patients at high risk for preterm birth. In these high-risk women, treat with an oral metronidazole for ≥1 wk | A meta-analysis has shown benefit with this treatment in women with high-risk pregnancies. |
| Treat symptomatic *Trichomonas vaginalis* infection to relieve maternal symptoms, but do not screen for or treat asymptomatic trichomoniasis | This opinion is based on randomized trials in asymptomatic infected women. |
| Do not treat *Ureaplasma urealyticum* genital colonization | One double-blind treatment trial that corrected for confounding infections showed no benefit. |
| Do not treat group B streptococcal genital colonization | One double-blind treatment trial showed no benefit. |
| ***With Preterm Labor and Intact Membranes*** | |
| Give group B streptococcal prophylaxis to prevent neonatal sepsis | As recommended by Centers for Disease Control and Prevention and American College of Obstetricians and Gynecologists. |
| Do not give antibiotics routinely to prolong pregnancy | A meta-analysis concluded that antibiotics gave no neonatal benefit. |
| ***With Preterm Premature Rupture of Membranes*** | |
| Give group B streptococcal prophylaxis to prevent neonatal sepsis | As recommended by Centers for Disease Control and Prevention and American College of Obstetricians and Gynecologists. |
| Give additional antibiotics in pregnancies at 24 to 32 wk | Meta-analyses concluded that there was substantial benefit to the neonate. |

regarding selection of resistant organisms and masking of infection. To date, evidence of selection pressure has been limited mainly to infants with very low birth weight [179]. Masking infection is now of great concern, especially in view of evidence that intrauterine exposure to bacteria is associated with long-term adverse neonatal outcomes including cerebral palsy and PVL [99,110].

For reasons other than prevention of preterm birth, detection and treatment of *N. gonorrhoeae*, *C. trachomatis*, and bacteriuria are appropriate. Table 3–10 summarizes our recommendations for use of antibiotics to prevent preterm birth. Future research is urgently needed, however, to identify markers in women who are in preterm labor as a result of infection, in whom intervention with antibiotics or other novel therapies is most likely to be beneficial. In addition, detection of women genetically predisposed to infection-induced preterm birth is important. Some investigators have identified associations between polymorphisms in the cytokine gene complexes including TNF-α and preterm PROM or spontaneous preterm birth [113–115,180].

## PREMATURE RUPTURE OF MEMBRANES

PROM is a common but poorly understood problem. Because there is little understanding of its etiology, management has been largely empirical, and obstetricians have been sharply divided over what constitutes the best approach to care [181–184]. The problem is complex. Gestational age and demographic factors influence the outcome with PROM. Therapeutic modalities added within the past 2 decades include corticosteroids, tocolytics, and more potent antibiotics, but their place in therapy is controversial. Of major importance is the marked improvement in survival of infants with low birth weight. This chapter emphasizes developments since 1970. The literature has been reviewed periodically.

### DEFINITION

Lack of standard, clear terminology has hindered understanding of PROM. Most authors define PROM as rupture at any time before the onset of contractions, but "premature" also carries the connotation of preterm pregnancy. To avoid confusion, we reserve "preterm" to refer to rupture occurring at a gestational age less than 37 weeks. Others using the expression "prolonged rupture of the membranes" have used the same acronym, PROM.

The latent period is defined as the time from membrane rupture to onset of contractions. It is to be distinguished from the latent phase, which designates the phase of labor that precedes the active phase. "Conservative" or "expectant" management refers to the period of watchful waiting when IAI has been clinically excluded in the setting of PROM.

In addition to IAI, terms used to describe maternal or perinatal infections during labor include fever in labor, intrapartum fever, chorioamnionitis, amnionitis, and intrauterine infection. In most reports, clinical criteria used for these diagnoses include fever, uterine irritability or tenderness, leukocytosis, and purulent cervical discharge. After

delivery, maternal uterine infection is referred to an endometritis, endomyometritis or metritis. These clinical diagnoses usually are based on fever and uterine tenderness. In a few studies, presumed maternal infections were confirmed by blood and genital tract cultures.

For neonates, the most common term used to report infection is neonatal sepsis. Some authors use a positive blood or cerebrospinal fluid culture result, whereas others use clinical signs of sepsis without bacteriologic confirmation.

## INCIDENCE

In several reports, the incidence of PROM has ranged from 3% to 7% of total deliveries [185,186], whereas PROM related to preterm birth has occurred in approximately 1% of all pregnancies [10–12]. In some referral centers, preterm PROM accounted for 30% of all preterm births. Despite some progress in prolonging the latent period after preterm PROM and possible prevention of recurrence (e.g., by use of progesterone or by treating bacterial vaginosis), preterm PROM remains a leading contributor to the overall problem of premature birth.

## ETIOLOGY

Several clinical variables have been associated with PROM [187,188], including cervical incompetence, cervical operations and lacerations, multiple pregnancies, polyhydramnios, antepartum hemorrhage, and heavy smoking. In most instances, none of these clinical variables are present, however. No association has been found between the frequency of PROM and maternal age, parity, maternal weight, fetal weight and position, maternal trauma, or type of maternal work [181,189]. The NICHD Maternal-Fetal Medicine Units Network found that the combination of short cervical length, previous preterm birth caused by preterm PROM, and positive fetal fibronectin screening results was highly associated with preterm delivery caused by preterm PROM in the current gestation [190].

Physical properties of membranes that rupture prematurely also have been investigated. Studies of the collagen content of amnion in patients with PROM have led to conflicting results, perhaps because of important differences in methodology. Patients with Ehlers-Danlos syndrome, a hereditary defect in collagen synthesis, are at increased risk of preterm PROM. Other reports have shown that membranes from women with PROM are thinner than membranes from women without PROM [189]. Using in vitro techniques to measure rupturing pressure, investigators have found that the membranes from patients with PROM withstand either the same or higher pressure before bursting than do membranes from women without PROM [191,192]. Such observations have suggested a local defect at the site of rupture, rather than a diffuse weakening, in membranes that rupture before labor. These studies of physical properties should be interpreted with caution because of differences in measuring techniques, possible deterioration of membrane preparations, and need for proper controls.

In addition to being a possible cause of premature labor, subclinical infection may be a cause of PROM (see previous section). Acute inflammation of the placental membranes is twice as common when membranes rupture within 4 hours before labor than when they rupture after the onset of labor, which suggests that this “infection” may be the cause of PROM [193]. Supporting this hypothesis, increases in amniotic fluid MMP-1, MMP-8, and MMP-9 and decreases in MMP-1 and MMP-2 inhibitors have been shown in women experiencing preterm PROM [194,195].

Several reports have suggested a relationship among coitus, histologic inflammation, and PROM. In additional analyses, two successive singleton pregnancies in each of 5230 women (10,460 pregnancies) were considered [196]. Preterm PROM occurred in only 2% of 773 pregnancies when there was no recent coitus and histologic chorioamnionitis, but it occurred in 23% of 96 pregnancies when both of these features were present. A causal role of coitus or infection was not established, however, because there may have been other factors that were not considered. Evaluation of successive pregnancies would not have eliminated these confounding variables. In the South African black population, the rates of histologic chorioamnionitis and PROM were increased when coitus had occurred within the last 7 days. Use of a condom during coitus resulted in less placental inflammation. In addition, PROM occurred more often ($P > .01$) when there had been male orgasm during coitus [197]. Because organisms may attach to sperm, it has been hypothesized that sperm carry organisms into the endocervix or uterus.

Further evidence is provided by bacteriologic studies. Patients with PROM before term or with prolonged membrane rupture are more likely to have anaerobes in endocervical cultures than women without PROM at term [198,199]. These observations may be interpreted as showing that subclinical anaerobic “infection” leads to PROM. The increased presence of anaerobes in cervical cultures may reflect hormonal or other influences at different stages of gestation, however.

Investigations of risk factors for preterm PROM are likely to provide insight into the etiology of this condition. In the largest case-control study, Harger and colleagues reported 341 cases and 253 controls [200]. Only three independent variables were associated with preterm PROM in a logistic regression analysis: previous preterm delivery (OR 2.5, 95% CI 1.4 to 2.5), uterine bleeding in pregnancy, and cigarette smoking. OR accompanying bleeding increased with bleeding in late pregnancy and with the number of trimesters in which bleeding occurred (OR for first-trimester bleeding 2.4, 95% CI 1.9 to 23; OR for bleeding in more than one trimester 7.4, 95% CI 2.2 to 26). For cigarette smoking, OR was higher for women who continued smoking (OR 2.1, 95% CI 1.4 to 3.1) than for women who stopped (OR 1.6, 95% CI 0.8 to 3.3). Because previous preterm pregnancy is a historical feature and little can be done to prevent bleeding in pregnancy, this study provides an additional reason to encourage all patients, especially women of reproductive age, to stop smoking. Finally, in most cases, the specific etiology of preterm PROM is unknown.

## DIAGNOSIS

In most cases, PROM is readily diagnosed by history, physical findings, and simple laboratory tests such as determination of pH (Nitrazine [phenaphthazine] test

[Bristol-Myers Squibb, Princeton, NJ]) or detection of ferning. Although these tests are accurate in approximately 90% of cases, they yield false-positive and false-negative results, especially in women with small amounts of amniotic fluid in the vagina. If the patient is not going to be delivered immediately, a digital examination should be deferred because examination may introduce bacteria into the uterus and shorten the latent phase.

Other biochemical and histochemical tests and intra-amniotic injection of various dyes have been suggested, but they have not gained wide acceptance. Indigo carmine blue (1 mL diluted in 9 mL of sterile normal saline solution) can be injected into the amniotic fluid, and a sponge can be placed into the vagina and inspected 30 minutes later for dye. Methylene blue should not be used because of reported methemoglobinemia in the fetus. This test is invasive, and the accuracy of diagnosis is unknown.

An immunoassay for placenta $\alpha_1$-microglobulin (abundant in amniotic fluid, but barely detectable in normal cervicovaginal secretions) has been approved for detecting PROM. Initial reports have found high diagnostic accuracy [29,201].

Ultrasound examination also has been used as a diagnostic technique because oligohydramnios supports a diagnosis of PROM. Oligohydramnios has many additional causes, however. Ultrasound examination should be considered in the context of the entire clinical picture.

## NATURAL HISTORY

The onset of regular uterine contractions occurs within 24 hours after membrane rupture in 80% to 90% of term patients [2]. The latent period exceeds 24 hours in 19% of patients at term and exceeds 48 hours in 12.5% [200,202]. Only 3.6% of term patients do not begin to labor within 7 days [200].

Before term, latent periods are longer among patients with PROM. Confirming earlier studies, more recent investigations have shown latent periods of 24 hours in 57% to 83% [202,203], of 72 hours in 15% to 26% [204–206], and of 7 days in 19% to 41% of patients [202,204]. There is an inverse relationship between gestational age and of patients with latent periods of 3 days [205]. There is also an inverse relationship between advancing gestation and a decreased risk of chorioamnionitis. One third of women with pregnancies between 25 and 32 weeks of gestation had latent periods of 3 days, whereas for pregnancies between 33 and 34 weeks and between 35 and 37 weeks, the values were 16% and 4.5%. In 53 cases of PROM at 16 to 25 weeks (mean 22.6 weeks), the median length of time from PROM to delivery was 6 days (range 1 to 87 days, mean 17 days) [207]. In a population-based study of 267 cases of PROM before 34 weeks, 76% of women were already in labor at the time of admission, and an additional 5% had an indicated delivery. Only 19% were candidates for expectant management, and of these women, 60% went into labor within 48 hours [208]. The natural history of PROM reveals that labor usually develops within a few days.

In a few cases of PROM, the membranes can "reseal," especially with rupture of membranes after amniocentesis. With expectant management, 2.8% to 13% may anticipate the cessation of leakage of amniotic fluid [209,210].

## COMPLICATIONS

Analysis of complications described in more recent studies is complex because of differences in study design. Table 3–11 summarizes complications observed in studies with more than 100 infants. Direct comparisons of data from one study to another require extreme caution. The wide-ranging differences are attributable to major differences in populations at risk, gestational age, definitions, and management.

The most common complication among cases with PROM before 37 weeks is RDS, which is found in 10% to 40% in neonates. (A few studies have reported RDS in 60% to 80% of newborns.) Neonatal sepsis was documented in less than 10%, whereas amnionitis (based on clinical criteria only) occurred in 4% to 60% [211]. Endometritis developed in 3% to 29% of patients in most reports, but it is unclear whether patients with amnionitis are included in the endometritis category. In selected groups, such as women who undergo cesarean section after PROM, endometritis can occur in 70% of patients. Abruptio placentae after PROM is reported in 4% to 6% of cases, severalfold higher than the rate of 0.5% to 1% in the general population [212].

When latent periods in preterm pregnancies are prolonged, pulmonary hypoplasia is an additional neonatal complication. Although the rate of pulmonary hypoplasia seems to depend on the gestational age of PROM and the remaining amount of amniotic fluid surrounding the fetus, reported rates vary [213–215]. Vergani and colleagues reported that if severe oligohydramnios is present, there is nearly a 100% probability of lethal pulmonary hypoplasia when PROM occurs before 23 weeks [215]. Other investigators reported that the incidence of pulmonary hypoplasia is approximately 60% when rupture occurs before 19 weeks, however [216]. Nimrod and associates showed a 27% incidence of pulmonary hypoplasia in cases in which PROM occurred before 26 weeks and with long intervals (e.g., >5 weeks) between

**TABLE 3–11** Complications in Newborns after Premature Rupture of Membranes*

| Complication | Rate (%) |
|---|---|
| Perinatal mortality, overall | 0-43 |
| Term | 0-2.5 |
| All preterm | 2-43 |
| 1000-1500 g | 29 |
| 1501-2500 g | 7 |

| Amnionitis | 4-33 |
| Maternal (overall) | 3-29 |
| Endometritis | 3-29 |
| Neonatal sepsis | 0-7 |
| Neonatal overall (including clinically diagnosed sepsis) | 3-281 |

*Studies with >100 infants.
RDS, respiratory distress syndrome.

rupture and delivery [214]. Other studies showed a lower incidence of pulmonary hypoplasia [213]. Pulmonary hypoplasia is rare if PROM occurs after 26 weeks of gestation [215]. Pulmonary hypoplasia is poorly predicted antenatally by ultrasound examination [213]. Ultrasound estimates of interval fetal lung growth include lung length, chest circumference, chest circumference–abdominal circumference ratio, or chest circumference–femur length ratio.

In addition to the risk of pulmonary hypoplasia, an additional 20% of neonates had fetal skeletal deformities as a result of compression. Nonskeletal restriction deformities of prolonged intrauterine crowding similar to features of Potter syndrome include abnormal facies with low-set ears and epicanthal folds. Limbs may be malpositioned and flattened [217].

Low Apgar scores (<7 at 5 minutes of life) are noted in 15% to 64% of live-born infants [186,187,218–219]. This complication is most common among infants with very low birth weight. Other complications of PROM, especially in preterm pregnancies, include malpresentation, cord prolapse, and congenital anomalies. In view of the long list of potential hazards, it is not surprising that premature infants surviving after PROM often are subject to prolonged hospitalization.

Perinatal mortality depends mainly on gestational age. The wide variation in results for preterm infants reflects different groupings of gestational ages. It is uncertain whether infants with PROM have higher mortality than infants of the same gestational age without PROM.

Causes of perinatal death may be determined by examining data from four large series (Table 3–12) [185,188,220]. Two of these studies included stillbirths; two studies excluded them. Overall, RDS was the leading cause of death. Deaths were presumed to be due to hypoxia when there was an antepartum or intrapartum death of a very small infant. In frequency and severity, RDS was a greater threat than infection to the preterm fetus.

Maternal mortality as a complication of PROM is rare. Studies have documented only one maternal death (related to chorioamnionitis, severe toxemia, and cardiorespiratory arrest) in more than 3000 women with PROM [221]. Case reports of maternal death from sepsis complicating PROM appear sporadically [222].

**TABLE 3–12** Primary Causes of Death among Preterm Infants Born with Premature Rupture of Membranes

## APPROACH TO DIAGNOSIS OF INFECTION

Because of the frequency and potential severity of maternal and fetal infections after PROM, various tests have been studied as predictors of infection. One review critically appraised eight tests and found no test to be ideal [223]. A rectovaginal culture for GBS should be taken, unless the GBS status is already known. In addition, all patients with preterm PROM should receive a thorough physical examination focusing on possible evidence of chorioamnionitis. Digital examination should be avoided in patients with PROM, unless delivery is imminent. In a comparison of outcomes, women with digital examination after PROM had a significantly shorter latent period (2.5 $\pm$ 4 days versus 11.3 $\pm$ 13.4 days; $P < .001$), more maternal infections (44% versus 33%; $P = .09$), and more positive amniotic fluid cultures (11 of 25 [44%] versus 10 of 63 [16%]; $P < .05$) [224].

Abnormal physical examination findings that could support a diagnosis of chorioamnionitis include maternal or fetal tachycardia; uterine tenderness; and detection of a purulent, foul-smelling discharge. Temperature is often a late sign of chorioamnionitis, especially in preterm PROM.

Several authors have evaluated the use of amniocentesis and microscopic examination of amniotic fluid. Analyses for possible IAI include performing a Gram stain; glucose concentration; and cultures for anaerobes, aerobes, and genital mycoplasmas. A low amniotic fluid glucose can predict a positive amniotic fluid culture. When the glucose is greater than 20 mg/dL, the likelihood of a positive culture is less than 5%; when glucose is less than 5 mg/dL, the likelihood of a positive culture approaches 90% [55,225]. In addition, an elevated IL-6 in amniotic fluid may be the most sensitive predictor of intrauterine infection. Measurement of IL-6 in amniotic fluid is not a widely available test at this time, however.

Clinical infection is more common in women with positive smears or cultures, but 20% to 30% of these women or their newborns had no clinical evidence of infection [226–229]. In addition, amniocentesis may potentially be accompanied by trauma, bleeding, initiation of labor, or introduction of infection, although Yeast and colleagues reported no increase in onset of labor and no trauma in their retrospective series [230]. Table 3–13 summarizes the diagnostic and prognostic value of several tests of amniotic fluid.

Because the value of amniocentesis in patients with preterm PROM has not been determined precisely, most practitioners do not employ this test routinely for several reasons. Most patients with PROM and positive amniotic fluid culture results are in labor within 48 hours, and culture results are often delayed and available after the fact. Because some patients have positive culture results with no clinical evidence of infection, there is concern regarding unnecessary delivery of preterm infants. Finally, it has not been shown that clinical decisions based on data from amniocentesis lead to an improved perinatal outcome. Feinstein and colleagues evaluated 73 patients with preterm PROM who underwent amniocentesis [231]. When the Gram stain or culture result was positive, delivery was accomplished. Results were compared with 73 matched controls from a historical group. Compared with controls, patients managed by amniocentesis had less clinically diagnosed amnionitis (7% versus 20%, $P < .05$) and

**TABLE 3–13** Diagnostic Values of Amniotic Fluid Testing in Detection of Positive Amniotic Fluid Culture in Patients with Preterm Labor and Intact Membranes

| Diagnostic Index | Sensitivity | Specificity | Positive Predictive Value | Negative Predictive Value |
|---|---|---|---|---|
| Gram stain | 7/11 (63.64%) | 108/109 (99.08%) | 7/8 (87.50%) | 108/112 (96.43%) |
| IL-6 (≥11.30 ng/mL) | 11/11 (100%) | 90/109 (82.57%) | 11/30 (36.67%) | 90/90 (100%) |
| WBC count (≥50 cells/mm³) | 7/11 (63.64%) | 103/109 (94.50%) | 7/13 (53.85%) | 103/107 (96.26%) |

fewer low Apgar scores for their infants at 5 minutes (3% versus 12%, $P < .05$). There were no significant differences, however, in rates of overall infection (22% versus 30%), "possible neonatal sepsis" (12% versus 14%), or perinatal deaths (1% versus 3%).

Although there were apparent advantages to management by amniocentesis, controlled studies have serious limitations, and no significant decreases in overall infection or perinatal mortality were found. In a small comparative study of expectant management versus the use of amniocentesis, Cotton and associates reported a significantly shorter neonatal hospital stay in the amniocentesis group ($P < .01$), but more than 25% of patients were excluded because no amniotic fluid pocket was seen [232]. Also, there were no significant differences in rates of maternal infection, neonatal sepsis, or neonatal death. Ohlsson and Wang found Gram stain and culture of amniotic fluid to have a modest positive predictive value for clinical chorioamnionitis [226]. Clear evidence for the widespread use of amniocentesis in PROM is unavailable. In view of information regarding the association of cerebral palsy and infection, these issues should be reinvestigated in a controlled fashion.

Noninvasive procedures such as measuring the level of maternal serum C-reactive protein, measuring the level of IL-6 in vaginal secretions, and assessment of amniotic fluid volume have also been suggested as predictors of infection. Several groups have evaluated C-reactive protein as such a predictor [233–237]. An elevated level of C-reactive protein in serum from patients with PROM has a modest positive predictive value for histologic amnionitis (40% to 96%), but its predictive value for clinically evident infection is poor (10% to 45%). The value of a normal level of C-reactive protein for predicting absence of clinical chorioamnionitis is better (80% to 97%). In view of the low predictive value of a positive test, a decision to attempt delivery based solely on an elevated C-reactive protein level does not seem wise.

Kayem and colleagues [238] evaluated the diagnostic value of an IL-6 bedside test of vaginal secretions for neonatal infection in cases of preterm PROM. They showed that the sensitivity of this new test of IL-6 for the prediction of neonatal infection was 79% (95% CI 65 to 92), and its specificity was 56% (95% CI 42 to 70). Similar to evaluation of IL-6 in amniotic fluid, this immunochromatographic test is not widely available.

Women who have PROM with oligohydramnios seem to be at increased risk for clinically evident infection, but the positive predictive value is modest (33% to 47%). In 1985, Gonik and coworkers noted that "amnionitis" developed in 8 (47%) of 17 patients with no pocket of amniotic fluid larger than 1 × 1 cm on ultrasound examination, whereas amnionitis developed in 3 (14%) of 22 patients with adequate pockets (i.e., >1 × 1 cm) ($P < .05$) [239]. To improve the predictability of these tests, Vintzileos and colleagues used a biophysical profile that included amniotic fluid volume, fetal movement and tone, fetal respirations, and a nonstress test [240]. Positive predictive value of the biophysical profile has been variable (31% to 60% for clinical chorioamnionitis and 31% to 47% for neonatal sepsis) [226].

## TREATMENT OF PRETERM PREMATURE RUPTURE OF MEMBRANES BEFORE FETAL VIABILITY

Because fetal viability is nil throughout nearly all of the second trimester, the traditionally recommended approach to PROM in this period of gestation has been to induce labor. Retrospective reports have provided pertinent data on expectant management for PROM before fetal viability, however [208,241–244]. As expected, the latent period is relatively long (mean 12 to 19 days, median 6 to 7 days). Although maternal clinically evident infections were common (amnionitis in 35% to 59% and endometritis in 13%

to 17%) in these reports, none of these infections were serious; however, maternal death from sepsis has been reported [243,244]. There was an appreciable neonatal survival rate of 13% to 50%, depending on gestational age at membrane rupture and duration of the latent period. In cases with PROM at less than 23 weeks, the perinatal survival rate was 13% to 47%; with PROM at 24 to 26 weeks, it was 50% [243,244]. The incidence of stillbirth is greater (15%) with mid-trimester preterm PROM than with later preterm PROM (1%). The incidence of lethal pulmonary hypoplasia is 50% to 60% when membrane rupture occurs before 19 weeks [213].

With appropriate counseling, expectant management may be offered even in the second trimester for selected cases of PROM (Table 3–14). As neonatal survival in the previable periods continues to improve, the numbers of infants with moderate to severe disabilities remains substantial [245]. These concerns should be clearly communicated to the mother before delivery. As discussed subsequently, a plan for GBS surveillance and treatment also would be indicated.

**TABLE 3–14** Summary of Management Plans for Premature Rupture of Membranes

| Management | Evidence |
|---|---|
| ***In Second Trimester (<26-28 wk)*** | |
| Induction | |
| Expectant management | Retrospective works show high maternal infection rate but 13-50% neonatal survival |
| ***In Early Third Trimester (26-34 wk)*** | |
| Tocolytics to delay delivery | Randomized trials show no important benefits |
| Corticosteroids to accelerate lung maturity 32 wk | CDC consensus statement recommends use between 24 and 32 wk |
| Antibiotics for prophylaxis of neonatal group B streptococcal infection | Efficiency established in randomized trial |
| Antibiotics to prolong latent period | Risk-benefit ratio unresolved; limit to randomized trials; optimal duration of antibiotics unresolved |
| Expectant management | Approach followed most commonly; if premature rupture of membranes occurs >32 wk, randomized trials show no neonatal benefit to expectant management |
| ***At or Near Term (>35 wk)*** | |
| Early induction, within 12-24 hr | |
| Late induction, after approximately 24 hr | |
| Expectant management until labor or infection develops | Evidence supports early induction and expectant management |
| Prostaglandin $E_1$ and $E_2$ preparations to ripen cervix and induce labor | Randomized trials and historical data support safety and efficacy |

## Investigational Treatment Measures

Highly experimental protocols are investigating the possibility of extrinsic materials to promote resealing of the amniotic membranes. This idea stems from the use of a blood patch for treatment of spinal headache [246]. An aggressive interventional protocol for early mid-trimester PROM using a gelatin sponge for cervical plugging in patients with spontaneous or iatrogenic preterm PROM at less than 22 weeks with significant oligohydramnios (maximum vertical pocket <1.5 cm) evaluated transabdominal or transcervical placement of the gelatin sponge. This measure was in addition to broad-spectrum antibiotic therapy and cervical cerclage. Eight of 15 women undergoing the procedure reached a late enough stage in gestation to allow fetal viability, and 3 (30%) infants survived to hospital discharge. Three of the surviving infants had talipes equinovarus, and two had bilateral hip dysplasia and torticollis.

Quintero [247] introduced an “amniopatch” consisting of autologous or heterologous platelets and cryoprecipitate through a 22-gauge needle intra-amniotically into seven patients with preterm PROM 16 to 24 weeks after fetoscopy or genetic amniocentesis and reported a fetal survival rate of 42.8% (three of seven). Of the remaining patients, two had unexplained fetal death, one miscarried, and a fourth had underlying bladder outlet obstruction that prevented resealing of membranes. With spontaneous rupture of membranes, zero of 12 patients have had resealing of their membranes [246]. Quintero speculated that with spontaneous rupture of membranes, rupture sites are larger, are located over the internal cervical os, are less amenable to patching, and are more susceptible to ascending infection and weakening of the lower portion of the membranes by proinflammatory agents.

To address the larger defect with spontaneous preterm PROM, Quintero and colleagues investigated the use of an “amnio graft,” achieved by laser-welding the amniotic membranes using Gore-Tex materials and a collagen-based graft material (Biosis) and combined use with a fibrin glue, with variable success in animal models and selected patients [246–248]. Use of a fibrin sealant was associated with a 53.8% survival rate when the sealant was placed transcervically. In their study, mean gestational age at rupture of membranes was 19 weeks 4 days; at treatment, 20 weeks 5 days; and at delivery, 27 weeks 4 days, with a mean latency of 48 days from initial rupture to delivery. Additional research in this area is necessary to establish the safety and efficacy of this modality.

# TREATMENT OF PRETERM PREMATURE RUPTURE OF MEMBRANES IN EARLY THIRD TRIMESTER

Management is most controversial at the gestational age interval of 24 to 34 weeks. New information has become available, however, and sophisticated meta-analyses have been performed. Controversial components of therapy, including corticosteroids, tocolytics, and antibiotics are reviewed here. Specific situations, such as herpes simplex virus and human immunodeficiency virus (HIV) infection and cerclage coexisting with PROM, are reviewed later.

Some studies reported significant (or nearly significant) decreases in the occurrence of RDS, but others found no

significant decrease when corticosteroids were used in patients with PROM [249–258]. There are major difficulties in interpreting these studies. In some of the more rigorously designed studies of corticosteroid use, the numbers of patients with PROM were small. The real differences may have been missed (a beta error). In most studies, there were at least small decreases in the incidence of RDS in the corticosteroid group. A wide range of gestational ages was studied. The minimum number of weeks of gestation for entry into a study was 25 to 32, and the maximum was 32 to 37. Because an equal effect of corticosteroids on the rate of RDS is unlikely at all gestational age intervals, real differences may have been missed in some intervals because data for these intervals were combined with data for other gestational ages. Finally, experiments measuring the surfactant-inducing potency of corticosteroids suggest differences in the efficacy of various corticosteroid preparations and various dosages.

Several studies, including three meta-analyses, have attempted to resolve the confusion [259–261]. The authors reached differing conclusions. Ohlsson concluded that in preterm PROM, corticosteroid treatment "cannot presently be recommended to prevent RDS ... outside a randomized controlled trial [259]. The reasons underlying this conclusion are that the evidence that it decreases RDS is weak and its use increases incidence of endometritis and may increase neonatal infections." Crowley concluded that corticosteroids were effective in preventing RDS after preterm PROM (OR 0.44, 95% CI 0.32 to 0.60) and that they were not associated with a significant increase in perinatal infection (OR 0.84, 95% CI 0.57 to 1.23) or neonatal infection (OR 1.61, 95% CI 0.9 to 3.0) [260]. Lovett and colleagues, in a prospective, double-blind trial of treatment for preterm PROM, used corticosteroids in all patients. They also found significant decreases in mortality, sepsis, and RDS rates and increased birth weight when corticosteroids and antibiotics were given compared with use of corticosteroids alone. Lewis and coworkers investigated use of ampicillin-sulbactam in preterm PROM and randomly assigned patients to receive weekly corticosteroids versus placebo between 24 and 34 weeks. They found a decrease in RDS (44% versus 18%; $P = .03$ or 0.29, 95% CI 0.10% to 0.82%) in the corticosteroid treatment group with no increase in maternal or neonatal infection complications [261].

Leitich and associates concluded that corticosteroids seem to diminish the beneficial effects of antibiotics in the treatment of preterm PROM. This conclusion was based on the results of their meta-analysis of five randomized trials of antibiotics and preterm PROM without corticosteroids. They found nonsignificant differences in mortality, sepsis, RDS, IVH, and necrotizing enterocolitis when antibiotics and corticosteroids were used. By contrast, when antibiotics without corticosteroids were used, they found a significant decrease in chorioamnionitis (OR 0.37, $P = .0001$), postpartum endometritis (OR 0.47, $P = .03$), neonatal sepsis (OR 0.27, $P = .002$), and IVH (OR 0.48, $P = .02$) [262].

The National Institutes of Health Consensus Development Panel in 1995 recommended that corticosteroids be given in the absence of IAI to women with preterm PROM at less than 30 to 32 weeks of gestation because the benefits of corticosteroids may outweigh the risk at this gestational age, particularly of IVH. Because the number of patients receiving corticosteroids with PROM at more than 32 weeks of gestation was small, the consensus panel chose to restrict its recommendation to less than 32 weeks of gestation. Recommended dosing includes betamethasone, 12 mg intramuscularly every 24 hours for two doses, or dexamethasone, 6 mg every 12 hours for four doses. The consensus panel reconvened in 2000 and reconfirmed their original recommendations. Repeat dosing of steroids was not recommended outside of randomized trials. A 2006 Cochrane Update on antenatal corticosteroids recommended a single course of corticosteroids for women at 24 to 34 weeks of gestation in whom there is reason to anticipate early delivery, including women with ruptured membranes. Weighing the hypothetical risk of increased infection when corticosteroids are used in preterm PROM, we use 32 weeks as the upper gestational age limit for use.

Lee and associates also evaluated use of weekly steroids in a randomized double-blind trial in women at 24 to 32 weeks of gestation with preterm PROM compared with a single course of steroids. Although investigators found no differences in the overall composite neonatal morbidity between the groups (34.2% versus 41.8%), they did find an increased rate of chorioamnionitis in the weekly course group (49.4% versus 31.7%; $P = .04$). In the group with gestational age at delivery of 24 to 27 weeks, there was a significant reduction in RDS from 100% in the single course group to 26.5% ($P = .001$) in the weekly course group [263]. Guinn and colleagues found no decrease in neonatal morbidity with serial weekly courses of betamethasone compared with single course therapy [236]. In the secondary analysis of this multicenter, randomized trial of weekly courses of antenatal corticosteroids versus single course therapy, this same group reported that multiple courses were associated with an increase in the rate of chorioamnionitis [263]. Based on the available information, antenatal steroid therapy in preterm PROM should be limited to a single course.

## Antibiotics

Patients with preterm PROM are candidates for prophylaxis against GBS [264–266]. In addition, one innovative report noted use of combination antibiotics in an asymptomatic patient with preterm PROM because of bacterial colonization of the amniotic fluid, which was detected by amniocentesis. A second amniocentesis 48 hours after therapy revealed a sterile culture [267].

Some studies of preterm pregnancies have found an increased rate of amnionitis to be associated with an increasing length of latent period [186,220,268], whereas others [219] have not. In patients with preterm PROM, digital vaginal examination should be avoided until labor develops, although transvaginal or transperineal ultrasound can be used safely to assess cervical length without increasing the risk of infection [269]. Some studies noted that prolonged rupture of membranes decreased the incidence of RDS [188,221], others noted no significant effect [185,204,219,220,250,270,271]. These discrepancies may be explained by differences in experimental design (e.g., grouping of various gestational ages and using different sample sizes) or in definitions of clinical complications.

Antibiotics in several classes have been found to prolong pregnancy and reduce maternal and neonatal

morbidity in the setting of preterm PROM [272]. Two large multicenter clinical trials with different approaches had adequate power to evaluate the utility of antibiotics in the setting of preterm PROM. Mercer and Arheart [116] evaluated the use of antibiotics in PROM with a meta-analysis. They evaluated such outcomes as length of latency, chorioamnionitis, postpartum infection, neonatal survival, neonatal sepsis, RDS, IVH, and necrotizing enterocolitis. Several classes of antibiotics were used, including penicillins and cephalosporins, although few studies used either tocolytics or corticosteroids. Benefits of antibiotics in this analysis included a significant reduction in chorioamnionitis, IVH, and confirmed neonatal sepsis. There was a significant decrease in the number of women delivering within 1 week of membrane rupture (OR 0.56, CI 0.41 to 0.76), but no significant differences were seen in necrotizing enterocolitis, RDS, or mortality. The evidence currently supports use of antibiotics in preterm PROM to prolong latency and to decrease maternal and neonatal infectious complications, but further studies to select the preferred agent have yet to be performed.

The NICHD Maternal-Fetal Medicine Units Network conducted a large, multicenter trial of antibiotics after PROM, but did not use tocolytics or corticosteroids. Patients with preterm PROM between 24 and 32 weeks were included. Patients were randomly assigned to receive aggressive intravenous antibiotic therapy consisting of ampicillin (2 g intravenously every 6 hours) and erythromycin (250 mg intravenously every 6 hours) for the first 48 hours, followed by 5 days of oral therapy of amoxicillin (250 mg every 8 hours) and enteric-coated erythromycin (333 mg orally every 8 hours) or placebo. Antibiotic treatment resulted in prolongation of pregnancy. Twice (50%) as many patients in the antibiotic treatment group remained pregnant after 7 days, and 21-day composite neonatal morbidity was reduced in the antibiotic treatment group from 53% to 44% ($P < .05$). In addition, individual neonatal comorbid conditions occurred less often in the antibiotic treatment group, including RDS (40.5% versus 48.7%), stage 3/4 necrotizing enterocolitis (2.3% versus 5.8%), patent ductus arteriosus (11.7% versus 20.2%), and bronchopulmonary dysplasia (13% versus 20.5%) ($P < .05$ for each). Occurrence rates for specific infections including neonatal GBS-associated sepsis (0% versus 1.5%), overall neonatal sepsis (8.4% versus 15.6%), and pneumonia (2.9% versus 7%) all were significantly less ($P < .05$) in the antibiotic treatment group.

The second large trial was the multicenter, multiarm ORACLE trial of oral antibiotics in women with preterm PROM at less than 37 weeks. More than 4000 patients were randomly assigned to receive oral erythromycin, amoxicillin/clavulanic acid, erythromycin and amoxicillin/clavulanic acid, or placebo for up to 10 days. All of the antibiotic regimens prolonged pregnancy compared with placebo. Amoxicillin/clavulanic acid increased the risk for neonatal necrotizing enterocolitis (1.9% versus 0.5%; $P = .001$), however, and this regimen is now advised against. The investigators showed a significant decrease in perinatal morbidity, RDS, and necrotizing enterocolitis with use of ampicillin and erythromycin [117].

Egarter and associates found in a meta-analysis of seven published studies a 68% reduction of neonatal sepsis and a 50% decreased risk of IVH in infants born to mothers receiving antibiotics after preterm PROM. They did not find any significant differences, however, in either RDS or neonatal mortality [273].

The Cochrane Library has reviewed antibiotic use in preterm PROM in more than 6000 women in 19 trials. This meta-analysis also found that antibiotic use in preterm PROM was associated with an increased latent period at 48 hours and 7 days and reduction in major neonatal comorbid conditions or indicators such as neonatal infection, surfactant use, oxygen therapy, and abnormalities on head ultrasound examination before hospital discharge. There was an increased risk of necrotizing enterocolitis in the two trials involving 2492 infants in which co-amoxiclav was administered to the mother (relative risk 4.6, 95% CI 1.98 to 10.72). Another trial in the meta-analysis compared erythromycin with co-amoxiclav; the investigators found fewer deliveries at 48 hours in the co-amoxiclav group, but no difference at 7 days. The trial also found a decrease in necrotizing enterocolitis when erythromycin rather than co-amoxiclav was used (relative risk 0.46, 95% CI 0.23 to 0.94) [274]. The investigators in this trial recommended that co-amoxiclav should be avoided in the setting of preterm PROM.

Owing to concerns of emergence of resistant organisms, another question involves duration of antibiotic therapy in preterm PROM. Two small trials have evaluated this question. Segel and associates compared 3 days and 7 days of ampicillin in patients at 24 to 33 weeks with preterm PROM. In 48 patients, there was no difference in 7-day latency and no difference in rates of chorioamnionitis, postpartum endometritis, and neonatal morbidity and mortality [275]. Lewis and colleagues studied 3 days versus 7 days of ampicillin/sulbactam (3 g intravenously every 8 hours) and similarly found no difference in outcomes between groups [276]. Both of these studies are small, so this important question remains unanswered. We use 7 days of antibiotics, usually ampicillin and erythromycin, following the dosing from the NICHD trial.

## Tocolytics and Development of Respiratory Distress Syndrome

Older studies suggested a decrease in the rate of RDS with use of β-adrenergic drugs, but in the National Collaborative Study, use of tocolytics in patients with ruptured membranes increased the likelihood of RDS by about 350% [277]. In addition, two small randomized controlled trials assessed use of tocolytics in the presence of PROM [278,279]. Both trials found no significant increase in time to delivery or in birth weight and no decrease in RDS or neonatal hospital stay. These studies did not use antibiotics or corticosteroids, however. Tocolytics have been shown to prolong pregnancy by about 48 hours in patients with intact membranes, but their efficacy with preterm PROM is unclear. In a patient with preterm PROM and contractions, IAI should be ruled out before consideration of tocolytics. Tocolytics could be considered in the early third trimester to maximize the impact of antenatal corticosteroids (48-hour delay) on neonatal morbidity and mortality. Continuing tocolysis beyond the 48-hour window is contraindicated because of an increase in

chorioamnionitis and endometritis [280]. Interested readers are referred to a review of this subject [281].

## Determination of Fetal Lung Maturity

Some clinicians determine the status of fetal pulmonary maturity and proceed with delivery if the lungs are mature. Amniotic fluid may be collected by amniocentesis or from the posterior vagina. Either the presence of phosphatidylglycerol or a lecithin/sphingomyelin ratio higher than 2 in amniotic fluid has been reported to be a good predictor of pulmonary maturity. In a series of patients with PROM before 36 weeks, Brame and MacKenna determined whether phosphatidylglycerol was present in the vaginal pool and delivered patients when there was presence of phosphatidylglycerol, spontaneous labor, or evidence of sepsis [282]. Of 214 patients, 47 had phosphatidylglycerol present initially and were delivered. Of the remaining 167, 36 (21%) were subsequently found to have phosphatidylglycerol and were induced or delivered by cesarean section. Evidence of maternal infection developed in 8 (5%) and spontaneous labor developed in 123 (74%) of the 167 patients. Phosphatidylglycerol in amniotic fluid from the vagina reliably predicted fetal lung maturity; however, its absence did not mean that RDS would develop. Of 131 patients who did not show phosphatidylglycerol in the vaginal pool in any sample, 82 (62%) were delivered of infants who had no RDS. Lewis and colleagues also showed the presence of a mature Amniostat-FLM (Hana Biologies, Irvine, CA) in a vaginal pool sample from 18% of 201 patients, and none developed RDS.

## Intentional Preterm Induction in Mid–Third Trimester

Even with PROM, delivery of a premature infant simply because the lungs show biochemical maturity may be questioned in view of other potential hazards of prematurity and the potential difficulties of the induction. Two articles have examined this controversial issue. With respect to the new information regarding the association among preterm PROM, chorioamnionitis, and subsequent development of cerebral palsy, the use of intentional mid–third trimester induction is receiving increased attention.

Mercer and colleagues compared expectant management and immediate induction in 93 pregnancies complicated by PROM between 32 and 36 weeks and 6 days, when mature fetal lung profiles were documented. They found significant prolongation of latent period and of maternal hospitalization, increased neonatal length of stay, and increased antimicrobial use in the expectant management group despite no increase in documented neonatal sepsis. These investigators concluded that in women with preterm PROM at 32 through 36 weeks with a mature fetal lung profile, immediate induction of labor reduces the duration of hospitalization in the mother and neonate [218,283].

Cox and Leveno similarly studied pregnancies complicated by preterm PROM at 30 to 34 weeks of gestation. Consenting patients were randomly assigned to one of two groups: expectant management versus immediate induction. Corticosteroids, tocolytics, and antibiotics were not used in either group. Fetal lung profiles were not determined. The investigators found a significant difference in birth weight or frequency of IVH, necrotizing enterocolitis, neonatal sepsis, RDS, or perinatal death. They concluded that there were no clinically significant neonatal advantages to expectant management of ruptured membranes and decreased antepartum hospitalization in women managed with immediate induction [284].

A more recent review evaluated 430 women with preterm PROM and evaluated maternal and neonatal outcomes. They found that expectant management of women at 34 weeks and beyond is of limited benefit [285]. Based on all available data, we routinely proceed with induction of labor at 34 weeks in patients with preterm PROM and no other indication for earlier delivery.

## Fetal Surveillance

Because of concerns regarding cord compression and cord prolapse and the development of intrauterine and fetal infection, daily fetal monitoring in the setting of preterm PROM has been studied. Vintzileos and colleagues showed that infection developed when the nonstress test became nonreactive 78% of the time compared with only 14% when the nonstress test remained reactive [286]. Biophysical profile score of 6 or less also predicted perinatal infection [287]. As a result, we recommend daily monitoring with nonstress tests. If the nonstress test is nonreactive, further work-up with biophysical profile should be performed. Because there are currently no large studies evaluating outpatient management of preterm PROM, we recommend hospitalization until delivery.

## Conclusion

Despite availability of more recent data and sophisticated meta-analyses, we believe the evidence supports the use of expectant management in the absence of IAI and in the absence of documented fetal lung maturity in the third trimester until 34 completed weeks. If expectant management is chosen, corticosteroids to enhance fetal organ maturation should be given until 32 weeks. In addition, broad-spectrum antibiotics consisting of ampicillin and erythromycin should be administered for 7 days. Bacterial vaginosis, if present, should also be treated. Tocolytics generally should be avoided. Daily fetal surveillance is also recommended. Appropriate prophylaxis for GBS in this high-risk group is strongly encouraged during labor. From a cost-effectiveness standpoint, Grable and others looked at preterm PROM between 32 and 36 weeks. Using their decision analysis based on 1996 cost data, they weighed the costs of maternal hospitalization, latency, infection, and minor and major neonatal morbidity versus that of immediate induction. These investigators found that it is most effective to delay delivery by 1 week between 32 and 34 weeks and to induce at presentation at or after 35 weeks [288,289].

# RECURRENCE OF PRETERM PREMATURE RUPTURE OF MEMBRANES

Recurrence of preterm PROM in a subsequent pregnancy after an index pregnancy complicated by preterm PROM has been estimated to be 13.5% to 44%. In Lee and colleagues' population-based case-control study, OR for recurrent preterm PROM was 20.6 and for recurrent preterm birth was 3.6. The estimated gestational age of index

preterm PROM is poorly predictive, however, of subsequent timing of recurrent events. The other two studies had higher recurrence of risks, but probably included transferred patients, so that the study populations constituted a more select group [196,290–292].

## PREVENTION OF PRETERM PREMATURE RUPTURE OF MEMBRANES

Because preterm PROM often is accompanied by maternal and neonatal adverse events, prevention of preterm PROM is desirable. Prediction of preterm PROM was evaluated in a large prospective trial, the Preterm Prediction Study [292], sponsored by the NICHD Maternal-Fetal Medicine Units Network. Prior preterm birth and preterm birth secondary to preterm PROM were associated with subsequent preterm birth. In nulliparas, preterm PROM is associated with medical complications, work in pregnancy, symptomatic contractions, bacterial vaginosis, and low body mass index. In nulliparas and multiparas, a cervix found to be shorter than 25 mm by endovaginal ultrasound examination was associated with preterm PROM. A positive fetal fibronectin also was predictive of preterm PROM in nulliparas (16.7%) and multiparas (25%). Multiparas with a prior history of preterm birth, a short cervix, and a positive fetal fibronectin had a 31-fold higher risk of PROM and delivery before 35 weeks compared with women without these risk factors (25% versus 0.8%; $P = .001$) [190]. Progesterone therapy seems to be effective in reducing the risk of recurrent preterm birth secondary to PROM or preterm labor [293–295].

## SPECIAL SITUATIONS

### Cerclage and Preterm Premature Rupture of Membranes

Classic obstetric dogma has suggested immediate removal of the cervical cerclage stitch when preterm PROM occurs. Risks associated with the retained stitch include maternal infection from bacterial proliferation emanating from the foreign body and cervical lacerations consequent to progression of labor despite the retained stitch. Small retrospective studies have shown conflicting results. At present, there are not enough data in the literature to recommend removal or retention of the suture. If there is no evidence of IAI or preterm labor in very premature gestations, one could consider leaving the stitch in during corticosteroid administration while there is uterine quiescence [296–300].

### Preterm Premature Rupture of Membranes and Herpes Simplex Virus

In a retrospective review from 1986-1996 of 29 patients with preterm PROM and a history of recurrent genital herpes, there were no cases of neonatal herpes. The 95% CI suggests, however, that the risk of vertical transmission could be 10%. The mean estimated gestational age at membrane rupture was 27.7 weeks. Mean estimated gestational age at development of maternal herpetic lesion was 28.7 weeks. With continued expectant management, mean estimated gestational age at delivery was 30.6 weeks in the study group. Of the 29 patients, 13 (45%) were delivered by cesarean section. Additionally, although delivery was performed for obstetric indication only, 8 of 13 patients undergoing cesarean section had active lesions as the only or a secondary indication for cesarean section. In this study, risk of neonatal death from complications of prematurity was 10%. Risk of major neonatal morbidity was 41%. The risks of major morbidity and mortality would have been considerably higher had there been iatrogenic delivery at the time of development of the herpetic lesion.

It seems prudent when there is a history of recurrent herpes simplex virus infection to continue expectant management in a significantly preterm gestation. In the setting of primary herpes (or nonprimary first episode), with the higher viral loads that entails, early delivery may prevent vertical transmission, but this has not been specifically studied. Only eight of the patients in this study received acyclovir treatment. Use of acyclovir for symptomatic outbreaks would theoretically reduce the risk of transmission and decrease the number of cesarean sections performed for presence of active lesions at the time of delivery [301]. Additionally, Scott and associates showed a decreased cesarean section rate in term patients with a history of recurrent herpes simplex virus infection [302].

### Human Immunodeficiency Virus and Preterm Premature Rupture of Membranes

There are no specific data regarding the subset of patients with preterm PROM who are seropositive for HIV. With highly active antiretroviral therapy (HAART) and a low viral load, expectant management of preterm PROM after clinical exclusion of IAI might be considered because the complications of prematurity with gestational age of less than 32 weeks, and certainly less than 28 weeks, are significant. With continued HAART, the risk of vertical transmission should remain low. The physician should discuss and document potential risks and benefits with the mother regarding the possibility of vertical transmission or neonatal morbidity and mortality. Intravenous infusion of zidovudine should be initiated at admission because latency can be unpredictably short in many patients with preterm PROM [303]. After a period of observation and no evidence of spontaneous preterm labor, intravenous zidovudine may be discontinued and oral HAART continued.

## TREATMENT OF TERM PREMATURE RUPTURE OF MEMBRANES

Approximately 8% of pregnant women at term experience PROM, although contractions begin spontaneously within 24 hours of membrane rupture in 80% to 90% of patients [211]. After more than 24 hours elapses following membrane rupture at term, the incidence of neonatal infection is approximately 1%, but this risk increases to 3% to 5% when clinical chorioamnionitis is diagnosed [304]. For many years, the practice in most institutions had been to induce labor in term patients within approximately 12 hours of PROM, primarily because of concerns about development of chorioamnionitis and neonatal infectious complications. More recently, three studies have shown that in most patients, expectant management can be safely applied. The designs of these three reports were different.

Kappy and associates reported a retrospective review in a private population [202]. Duff and colleagues performed a

randomized study of indigent patients with unfavorable cervix characteristics (<2 cm dilated, <80% effaced) and with no complications of pregnancy (e.g., toxemia, diabetes, previous cesarean section, malpresentation, meconium-stained fluid) [305]. In the patients assigned to the induction group, initiation of induction generally was 12 hours after rupture of membranes. The excess cesarean deliveries in the induction group were for failed induction. In the induction group, there was a higher probability of IAI. In the study by Conway and colleagues, all patients were observed until the morning after admission [306]. Induction of labor was then undertaken if the patient was not in labor.

Wagner and coworkers provided another variant by comparing early induction (at 6 hours after preterm PROM) with late induction (at 24 hours after PROM) [307]. In their population at a Kaiser Permanente hospital, the results favored early induction by shortening maternal hospital stay and decreasing neonatal sepsis evaluations. More recent work also has evaluated use of oral and vaginal prostaglandin preparations (prostaglandins $E_1$ and $E_2$) to ripen the cervix or induce labor after PROM at term. These preparations seem to be effective in shortening labor without increasing maternal or neonatal infection [308–310].

Hannah and colleagues evaluated four management schemes in women with PROM at term: (1) immediate induction with oxytocin, (2) immediate induction with vaginal prostaglandin $E_2$, (3) expectant management for up to 4 days followed by oxytocin induction, and (4) expectant management followed by prostaglandin $E_2$ induction. Although no differences in cesarean section rates or frequency of neonatal sepsis were found, an increase in chorioamnionitis was noted in the expectant management groups, and all deaths not caused by congenital anomalies occurred in the expectant management group. Patient satisfaction was higher in the immediate induction group. A secondary analysis showed five variables as independent predictors of neonatal sepsis: clinical chorioamnionitis (OR 5.89), presence of GBS (OR 3.08), seven to eight vaginal examinations (OR 2.37), duration of ruptured membranes 24 to 48 hours (OR 1.97), greater than 48 hours from membrane rupture to active labor (OR 2.25), and maternal antibiotics before delivery (OR 1.63) [311].

A more recent study investigated how the interval of membrane rupture and delivery affects the risk of neonatal sepsis and whether duration of labor (defined as the interval between onset of regular contractions and delivery) influences the risk [312]. The investigators showed that the risk of neonatal sepsis increased independently and nearly linearly with duration of membrane rupture up to 36 hours, with an OR of 1.29 for each 6-hour increase in membrane rupture duration. The risk also increased with increasing birth weight, increasing gestational age, primiparity, and male infant gender. Duration of labor was not an independent risk factor for neonatal sepsis.

We endorse immediate induction with oxytocin in women with PROM at term if the condition of the cervix is favorable and the patient is willing. If the condition of the cervix is unfavorable, induction with appropriate doses of prostaglandins may be used before use of oxytocin. Intrapartum antibiotic prophylaxis against GBS should be used according to the 2002 CDC guidelines [264], which emphasize universal screening of all gravidas at 35 to 37 weeks. All seropositive women should receive intravenous antibiotics in labor. Changes in the 2002 recommendations over the previous guidelines also include antibiotic guidelines for patients with high-risk and low-risk penicillin allergy and checking sensitivities owing to emerging antibiotic resistance, particularly resistance of erythromycin and clindamycin to GBS.

CHAPTER 4

# Developmental Immunology and Role of Host Defenses in Fetal and Neonatal Susceptibility to Infection

David B. Lewis ✪ Christopher B. Wilson

## CHAPTER OUTLINE

DOI: 10.1016/B978-1-4160-6400-8.00004-3

The human fetus and neonate are unduly susceptible to infection with a wide variety of microbes, many of which are not pathogenic in more mature individuals. This susceptibility results from limitations of innate and adaptive (antigen-specific) immunity and their interactions. This chapter focuses on the ontogeny of the immune system in the fetus, neonate, and young infant and the relationship between limitations in immune function and susceptibility to specific types of infection.

The immune system includes innate protective mechanisms against pathogens provided by the skin, respiratory and gastrointestinal epithelia, and other mucosa; humoral factors such as cytokines (Tables 4–1 and 4–2) and complement components (Fig. 4–1); and innate and adaptive immune mechanisms mediated by hematopoietic cells, including mononuclear phagocytes, granulocytes, dendritic cells (DCs), and lymphocytes. Certain nonhematopoietic cells, such as follicular DCs and thymic epithelial cells, also play important roles in adaptive immunity.

Innate immunity, in contrast to adaptive immunity to be discussed later, does not require prior exposure to be immediately effective and is equally efficient on primary and subsequent encounter with a microbe, but does not provide long-lasting protection against reinfection. Innate defenses consist of fixed epithelial barriers and resident tissue macrophages, which act immediately or within the first minutes to hours of encounter with a microbe. These "frontline" defenses are sufficient for protection from most microbes in the environment, which do not produce disease in healthy individuals. If the microbial insult is too great, or the organism is able to evade these initial

**TABLE 4–1** Major Human Cytokines and Tumor Necrosis Factor (TNF) Family Ligands: Structure, Cognate Receptors, and Receptor-Mediated Signal Transduction Pathways

| Cytokine Family | Members | Structure | Cognate Receptor Family | Proximal Signal Transduction Pathways |
|---|---|---|---|---|
| IL-1 | IL-1α, IL-1β, IL-18 (IL-1γ), IL-1 receptor antagonist | β-trefoil, monomers; processed and secreted | IL-1 receptor | IRAK, JNK |
| Hematopoietin | IL-2 through IL-7, IL-9 through IL-13, IL-15, IL-17, IL-19, IL-29, CSFs, oncostatin-M, IFNs (α, β, γ, and others); class II subfamily consists of IL-10, IL-19, IL-20, IL-22, IL-24, IL-26, IFNs | Four α-helical; monomers except for IL-5 and IFNs (homodimers) and IL-12, IL-23, and IL-27 (heterodimers); secreted | Hematopoietin receptors | JAK tyrosine kinases/STAT, Src and Syk tyrosine kinases |
| TNF ligand | TNF-α, lymphotoxin-α, lymphotoxin-β, CD27L, CD30L, CD40L, OX40L, TRAIL, others | β-jellyroll, homotrimers; type II membrane proteins and secreted | TNF receptor family | TRAFs and proteins mediating apoptosis |
| TGF-β | TGF-β1, TGF-β2, TGF-β3, bone morphogenetic proteins | Cysteine knot; processed and secreted | TGF-β receptors type 1 and type 2 heterodimers (intrinsic serine threonine kinases) | Smad proteins |
| Chemokines | | Three-stranded β-sheet; all but fractalkine are secreted | Seven membrane-spanning domains | G protein–mediated |
| CXC ligand subfamily | CXCL1-14, CXCL16 | | CXCR1 through CXCR6 | |
| CC ligand subfamily | CCL1-5, CCL7, CCL8, CCL11, CCL13 through CCL28 | | CCR1 through CCR10 | |
| C ligand subfamily | XCL1 (lymphotactin), XCL2 (SCM-1β) | | XCR1 | |
| CX3C ligand subfamily | CX3CL (fractalkine) | | CX3CR1 | |

*CSF, colony-stimulating factors; IFN, interferon; IL, interleukin; IRAK, IL-1 receptor–associated serine/threonine kinase; JNK, c-Jun N-terminal kinase; STAT, signal transducer and activator of transcription; TGF, transforming growth factor; TRAFs, TNF-α receptor–associated factors; TRAIL, TNF-related apoptosis–inducing ligand.*

**TABLE 4–2** Immunoregulatory Effects of Select Cytokines, Chemokines, and Tumor Necrosis Factor (TNF) Ligand Family Proteins

| Cytokine | Principal Cell Source | Major Biologic Effects |
|---|---|---|
| IL-1α, IL-1β | Many cell types; Mϕ are a major source | Fever, inflammatory response, cofactor in T- and B-cell growth |
| IL-2 | T cells | T-cell > B-cell growth, increased cytotoxicity by T and NK cells, increased cytokine production and sensitivity to apoptosis by T cells, growth and survival of regulatory T cells |
| IL-3 | T cells | Growth of early hematopoietic precursors (also known as multi-CSF) |
| IL-4 | T cells, mast cells, basophils, eosinophils | Required for IgE synthesis; enhances B-cell growth and MHC class II expression; promotes T-cell growth and $T_H2$ differentiation, mast cell growth factor; enhances endothelial VCAM-1 expression |
| IL-5 | T cells, NK cells, mast cells, basophils, eosinophils | Eosinophil growth, differentiation, and survival |
| IL-6 | Mϕ, fibroblasts, T cells | Hepatic acute-phase protein synthesis, fever, T- and B-cell growth and differentiation |
| IL-7 | Stromal cells of bone marrow and thymus | Essential thymocyte growth factor |
| IL-8 (CXCL8) | Mϕ, endothelial cells, fibroblasts, epithelial cells, T cells | Chemotaxis and activation of neutrophils |
| IL-9 | T cells, mast cells | T-cell and mast cell growth factor |
| IL-10 | Mϕ, T, cells, B cells, NK cells, keratinocytes, eosinophils | Inhibits cytokine production by T cells and mononuclear cell inflammatory function; promotes B-cell growth and isotype switching, NK-cell cytotoxicity |
| IL-11 | Marrow stromal cells, fibroblasts | Hematopoietic precursor growth, acute-phase reactants by hepatocytes |
| TNF-α | Mϕ, T cells, and NK cells | Fever and inflammatory response effects similar to IL-1, shock, hemorrhagic necrosis of tumors, and increased VCAM-1 expression on endothelium; induces catabolic state |
| CD40 ligand (CD154) | T cells, lower amounts by B cells and DCs | B-cell growth factor; promotes isotype switching, promotes IL-12 production by dendritic cells, activates Mϕ |
| Fas ligand | Activated T cells, NK cells retina, testicular epithelium | Induces apoptosis of cells expressing Fas, including effector B and T cells |
| Flt-3 ligand | Bone marrow stromal cells | Potent DC growth factor; promotes growth of myeloid and lymphoid progenitor cells in conjunction with other cytokines |
| G-CSF | Mϕ, fibroblasts, epithelial cells | Growth of granulocyte precursors |
| GM-CSF | Mϕ, endothelial cells, T cells | Growth of granulocyte-Mϕ precursors and dendritic cells, enhances granulocyte-Mϕ function and B-cell antibody production |
| CCL3 (MIP-1α) | Mϕ, T cells | Mϕ chemoattractant; T-cell activator |
| CCL5 (RANTES) | Mϕ, T cells, fibroblasts, epithelial cells | Mϕ and memory T-cell chemoattractant; enhances T-cell activation; blocks HIV coreceptor |
| TGF-β | Mϕ, T cells, fibroblasts, epithelial cells, others | Inhibits Mϕ activation; inhibits $T_H1$ T-cell responses |

*CSF, colony-stimulating factor; DC, dendritic cell; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HIV, human immunodeficiency virus; IL, interleukin; Mϕ, mononuclear phagocytes; MHC, major histocompatibility complex; NK, natural killer; TGF, transforming growth factor; VCAM-1, vascular cell adhesion molecule-1.*

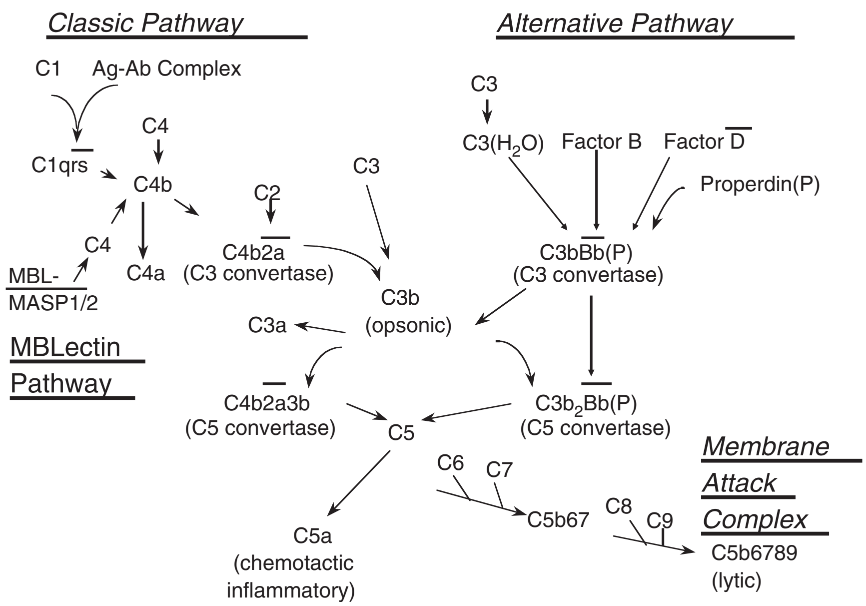

**FIGURE 4–1 Complement activation.** Classic and mannan-binding lectin (MBL) pathways of activation intersect with the alternative pathway at C3. MBL pathway of activation is identical to the classic pathway starting with the cleavage of C4. When C3 is activated, this is followed by activation of the terminal components, which generate the membrane attack complex (C5b6789). Enzymatically active proteases, which serve to cleave and activate subsequent components, are shown with an *overbar*.

defenses, these cells release mediators that incite an inflammatory response, through which soluble and cellular defenses are recruited and help to limit or eradicate the infection over the next hours to days and to initiate the antigen-specific immune response that follows.

## EPITHELIAL BARRIERS

Epithelia form a crucial physical and chemical barrier against infection. Tight junctions between epithelial cells prevent direct entry of microbes into deeper tissues, and physical injury that disrupts epithelial integrity can greatly increase the risk for infection. In addition to providing a physical barrier, mechanical and chemical factors and colonization by commensal microbes contribute to the protective functions of the skin and of the mucosal epithelia of the gastrointestinal and respiratory tract.

### ANTIMICROBIAL PEPTIDES

A general feature of epithelial defenses is the production of one or more antimicrobial peptides, which include the α-defensins, β-defensins and the cathelicidin LL-37. Defensins and cathelicidin have direct antimicrobial activity against gram-positive and gram-negative bacteria and some fungi, viruses, and protozoa [1–4]. Some of these antimicrobial peptides also exhibit proinflammatory and immunomodulatory activities.

There are six known human α-defensins: human neutrophil proteins (HNP) 1 through 4 and human defensins (HD) 5 and 6. HNP1 through HNP4 are expressed in leukocytes (white blood cells). HD5 and HD6 are produced and secreted by Paneth cells, located at the base of crypts in the small intestine. HD5 has antimicrobial activity against gram-positive and gram-negative bacteria and *Candida albicans*. There are at least six human β-defensins (hBD), but only four (hBD-1 through hBD-4) have been well characterized. hBD-1 is constitutively expressed by skin keratinocytes, whereas exposure to bacteria or proinflammatory cytokines, including tumor necrosis factor (TNF)-α and interleukin (IL)-1 (see Tables 4–1 and 4–2), induces expression of hBD-2 and hBD-3 in keratinocytes and hBD-4 in lung epithelial cells. hBD-1 and hBD-2 are active against gram-negative bacteria and streptococci, but are less active against *Staphylococcus aureus*, whereas hBD-3 is broadly active against gram-positive and gram-negative bacteria and *Candida* species. The cathelicidin LL-37 is expressed in leukocytes, and its expression is induced by microbes and proinflammatory cytokines in epithelial cells of the skin, gut, and respiratory tract; LL-37 is active against gram-positive and gram-negative bacteria, but less active against *S. aureus* than hBD-3 [5].

### SKIN

The barrier function of the skin is mediated primarily by its outermost layer, the stratum corneum, which consists of keratinocytes and the lipid-rich matrix that surrounds them [6]. These lipids, particularly ceramides, inhibit microbial growth, as does the low pH environment they help to create. The lipid content and acidic pH of the skin are established postnatally reaching maturity by 2 to 4 weeks in term neonates, but at a later age in premature neonates. Epithelial integrity and the antimicrobial barrier this provides are easily disrupted at this age. The skin of neonates is also coated by a water, protein, and lipid-rich material, the vernix caseosa. The skin is rapidly colonized by environmental bacteria after birth, creating a normal flora of commensal bacteria that help to prevent colonization by pathogens. This flora normally consists of coagulase-negative staphylococci, micrococci, and other species [7]. Contemporary genomics-based analyses of the flora of adult skin indicate that these and related gram-positive species represent only approximately 25% of the normal flora, with corynebacteria and other Actinobacteria predominating [8], but such approaches have not been applied to study the ontogeny of neonatal skin colonization.

Antimicrobial peptides are expressed by neonatal keratinocytes and present in the vernix caseosa. As in adults, the stratum corneum of skin from normal term neonates contains hBD-1 [9]. Neonatal skin also contains hBD-2 and LL-37 [9,10], which are absent or present only in very low amounts in the skin of normal adults. The mechanisms underlying the apparent constitutive production of hBD-2 and LL-37 by neonatal keratinocytes are unknown, but their presence may help to provide an immediate barrier against bacterial invasion during the initial exposure of the neonate to environmental microbes. The expression of LL-37 by the stratum corneum does not seem to be further upregulated in neonates with erythema toxicum, but this antimicrobial peptide is expressed by neutrophils, eosinophils, and DCs that are found in the dermis in this condition, which is thought to be triggered by colonizing bacteria. Vernix caseosa may augment skin defenses. Although the presence of LL-37 in vernix caseosa is controversial, being detected by one group, but not by another, both groups showed it to contain HNP1 through HNP3 and additional antibacterial proteins, including lysozyme [11,12].

### GASTROINTESTINAL TRACT

The proximal gastrointestinal epithelium of the mouth and esophagus consists of a squamous epithelium, whereas the stomach, small intestine, and colon have a columnar epithelium with microvilli, which, along with intestinal peristalsis, help to maintain the longitudinal movement of fluid. The acidic pH of the stomach acts as a chemical barrier in adults. Gastric acidification is not yet fully developed in neonates, but digestion of milk lipids by gastric lipases may compensate in part by generating free fatty acids [13]. The gastrointestinal tract is coated with a mucin-rich glycocalyx, which forms a viscous coating that helps to protect the epithelium and to which commensal intestinal bacteria bind [14]. The composition of the intestinal glycocalyx in neonates differs from adults and may contribute to differences in commensal flora.

The application of high-throughput, comprehensive, culture-independent molecular approaches to assess microbial diversity has shown that the commensal intestinal flora of humans is a highly diverse ecologic system

consisting of approximately $10^{14}$ microorganisms, representing the most abundant and diverse microbial community in the human body and exceeding the numbers and genetic content of human cells in an individual [8]. In adults, colonic and stool flora are dominated by gram-negative anaerobic bacteria (*Bacteroides*) and two phyla of gram-positive bacteria (Actinobacteria, Firmicutes), and aerobic gram-negative bacteria (e.g., *Escherichia coli*) are present in much lower abundance. The composition of stool flora in the first year of life is highly dynamic. Based on a longitudinal study of 14 term infants from whom serial samples were collected from birth to 1 year of age, the flora of individual infants differs substantially from one infant to another in the first months of life, initially most closely resembling the maternal fecal, vaginal, or breast milk flora [15]. This interindividual variability typically diminishes over time and by 1 year of age converges on a pattern similar to that found in adults. By contrast to older findings, which were based on culture-based methods, the flora of breast-fed infants was not dominated by bifidobacteria, which were rare in the first months after birth and thereafter represent only a small fraction of the total flora.

Although these findings are limited to a few healthy infants, they suggest that earlier views regarding normal stool and colonic flora and perhaps flora in other portions of the intestinal tract require revision. Future studies applying such approaches to compare systematically the flora of breast-fed infants versus formula-fed infants, infants delivered by different routes, infants born prematurely, and infants residing in the hospital versus the home should help us to understand better how such factors affect the intestinal flora and, perhaps, risk for necrotizing enterocolitis and other inflammatory, infectious, or allergic diseases in neonates and infants.

The dynamic interaction between host and microbe in the gut has an important impact on nutrition, intestinal homeostasis, and development of innate and adaptive immunity [14]. Such immunity restricts these microbes to the gut and primes the immune system to respond properly to dangerous microbes, while dampening the response to the normal flora, harmless environmental antigens, and self-antigens to prevent self-injury. Certain intestinal epithelial cells play special roles in intestinal immunity: Goblet cells produce mucus, Paneth cells (located at the base of small intestinal crypts) secrete antimicrobial factors, and M cells deliver by transcytosis a sample of the distal small intestinal microbiota to antigen-presenting DCs located beneath the epithelium; some DCs (the nature and function of which are discussed later) also directly sample the intestinal lumen of the distal small intestine.

The intestinal epithelium can directly recognize and respond to microbes using a limited set of invariant cell surface, endosomal, and cytosolic innate immune pattern recognition receptors, including toll-like receptors (TLRs) and others described later (see "Cytokine Production Induced by Engagement of Toll-like Receptors and Other Innate Immune Pattern Recognition Receptors"). How commensals prime innate and adaptive immunity in the gut without inducing deleterious inflammation, and how potentially dangerous pathogens are discriminated from harmless commensals are areas of active investigation. This discrimination is made in part by the location of commensals versus pathogens. Intestinal epithelial cells normally express little or no TLRs on their luminal surface—where they are in contact with commensals. Conversely, pathogens that invade through or between epithelial cells can be recognized by endosomal TLRs, cytosolic innate immune recognition receptors, and TLRs located on the basolateral surface of epithelial cells. Certain commensal bacteria inhibit signaling and inflammatory mediator production downstream of these receptors [14,16] or induce anti-inflammatory cytokine production [17], actively suppressing gut inflammation.

Adaptation of the intestinal epithelium to avoid unwarranted inflammatory responses to the normal flora is developmentally regulated or environmentally regulated, or both. Human 20- to 24-week fetal small intestinal organ cultures produced much more of the proinflammatory cytokine IL-8 (see Tables 4–1 and 4–2) when exposed to bacterial lipopolysaccharide (LPS) or IL-1 than similar cultures from infants or adults [18]. Studies in neonatal mice suggest that a general dampening of inflammatory signaling in intestinal epithelium occurs in response to postnatal colonization with commensal bacteria [19], but developmental differences may also be a factor. If so, and if this is also true in humans, such differences may contribute to aberrant intestinal inflammation in preterm neonates with necrotizing enterocolitis [20].

Intestinal epithelial cells produce and secrete defensins and other antimicrobial factors. Epithelial cells of the esophagus, stomach, and colon constitutively produce hBD-1 and the cathelicidin LL-37 and produce hBD-2, hBD-3, and hBD-4 in response to infection and inflammatory stimuli [21]. Intrinsic host defense of the small intestine is provided by Paneth cells, which constitutively produce HD5 and lysozyme [3]. The abundance of HD5 in the neonatal small intestine correlates with the abundance of Paneth cells—present but much less abundant in the fetus at mid-gestation than at term, which is much less abundant than in adults. These data suggest that intrinsic small intestinal defenses may be compromised in human neonates, particularly when preterm. A study in mice suggests another possibility, however. The intestinal epithelium of neonatal mice expresses abundant amounts of cathelicidin, which is lost by 14 days of postnatal age, by which time Paneth cells expressing murine defensins reach adult numbers [22]. It is unknown whether a similar "switch" in intestinal antimicrobial defenses occurs in humans.

## RESPIRATORY TRACT

The respiratory tract is second only to the gut in epithelial surface area. The upper airways and larger airways of the lung are lined by pseudostratified ciliated epithelial cells, with smaller numbers of mucin-producing goblet cells, whereas the alveoli are lined by nonciliated type I pneumocytes and by smaller numbers of surfactant-producing type II pneumocytes. Airway surface liquid and mucociliary clearance mechanisms provide an important first line of defense. Airway surface liquid contains numerous antimicrobial factors, including lysozyme, secretory leukoprotease inhibitor, defensins and cathelicidin

LL-37, and surfactant apoproteins A and D (SP-A, SP-D) [23]. Collectively, these factors likely account for the lack of microbes in the lower respiratory tract of normal individuals.

Lung parenchymal cells express a diverse set of TLRs and other innate immune receptors. Lower airway epithelial cells express and respond to ligands for TLR2, TLR4, and TLR5 [23–25]. The subcellular localization of these TLRs; the expression and localization of other TLRs; and the relative contribution of TLR-mediated microbial recognition by airway epithelial cells, other lung parenchymal cells, and lung macrophages are incompletely understood and areas of active investigation. Although, to our knowledge, there are no data carefully comparing TLR expression and function in the airways of the human fetus and neonate versus human adults, data from neonatal sheep (and rodents) indicate development differences. TLR2 and TLR4 are expressed in the lungs of fetal sheep in the latter part of gestation—messenger RNA (mRNA) abundance increases from 20% of adult values at the beginning of the third trimester to 50% at term [26]. TLR4 mRNA was present in the airway epithelium and parenchyma, whereas TLR2 expression was found primarily in inflammatory cells after intra-amniotic administration of LPS, which resulted in increased expression of TLR2 and TLR4. TLR3 expression was approximately 50% of adult values and unchanged in response to LPS. Similar developmental differences have been observed in mice [27].

Airway epithelial cells express hBD-1 constitutively and hBD-2, hBD-3, and LL-37 in response to microbial stimuli and inflammatory cytokines, including IL-1 [23]. Lung explants from term, but not preterm, fetuses expressed hBD-2 and smaller amounts of hBD-1, although the amounts even at term seemed to be less than at older ages, but did not contain hBD-3 mRNA [28]. By contrast, LL-37 mRNA was present and seemed not to vary at these ages. Consistent with these findings, tracheal aspirates from mechanically ventilated term, but not preterm, neonates contained hBD-2, whereas lower amounts of LL-37 were found in similar amounts in aspirates from preterm neonates. Another study found no difference in the abundance of hBD-1, hBD-2, and LL-37 in aspirates from ventilated neonates ranging in age from 22 to 40 weeks.

SP-A and SP-D are produced by type II pneumocytes and by Clara cells, which are progenitors of ciliated epithelial cells located at the bronchoalveolar junction. SP-A and SP-D are members of the collectin family. Collectins bind to carbohydrates, including mannose, glucose, and fucose, found on the surface of gram-positive and gram-negative bacteria, yeasts, and some viruses, including respiratory syncytial virus (RSV) [23,29]. When bound, collectins can result in aggregation of microbes, which may inhibit their growth or facilitate their mechanical removal, or can opsonize microbes (i.e., facilitate their ingestion by phagocytic cells). Mice lacking SP-A have impaired lung clearance of group B streptococci (GBS), *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and RSV [30,31]. Mice lacking SP-D also exhibit impaired clearance of RSV [31] and *P. aeruginosa* [30], and although they clear GBS normally, lung inflammation in response to this infection is more intense (reviewed by Grubor and colleagues [23] and Haagsman and colleagues [29]. SP-A and SP-D are detectable in human fetal lungs by 20 weeks of gestation [32], and amounts apparently increase with increasing fetal maturity and in response to antenatal steroid administration [33,34].

## SUMMARY

The skin of neonates, particularly preterm neonates, is more readily disrupted and lacks the protection provided by an acidic pH until approximately 1 month of postnatal age. Counterbalancing these factors is the constitutive production in neonates of a broader array of antimicrobial peptides by the skin epithelium and the presence of such peptides in the vernix caseosa. The lack of an acidic pH in the stomach may facilitate the establishment of the protective commensal flora, which at birth varies substantially from infant to infant, converging by 1 year of age to resemble adult flora. The lack of gastric acidity and diminished numbers of antimicrobial peptide–producing Paneth cells in the small intestine of preterm and, to a lesser degree, term neonates may increase their risk for enterocolitis and invasion by pathogens; these deficits may be counterbalanced by more robust production of antimicrobial peptides by other intestinal epithelial cells, but as yet this has been shown only in animal models. Innate defenses of the respiratory epithelium—TLRs, antimicrobial peptides, and SP-A and SP-D—are maturing in the last trimester. Consequently, these defenses may be compromised in preterm infants. Reduced numbers of resident alveolar macrophages may impair lung innate defenses further in preterm infants (see "Mononuclear Phagocytes").

# COMPLEMENT AND OTHER HUMORAL MEDIATORS OF INNATE IMMUNITY

## COLLECTINS AND PENTRAXINS

C-reactive protein (CRP) and mannose-binding lectin (MBL) are soluble proteins that can bind to structures found on the surface of microbes and infected or damaged host cells and facilitate their clearance by phagocytes. Both are produced by the liver. Their concentrations in the blood increase in response to infection and tissue injury as part of the acute-phase response, allowing them to contribute to early host defense to infection and the clearance of damaged cells.

CRP is a member of the pentraxin family of proteins [35], which binds to phosphocholine and other lipids and carbohydrates on the surface of certain gram-positive bacteria, particularly *Streptococcus pneumoniae*, fungi, and apoptotic host cells. It does not cross the placenta. Term and preterm neonates can produce CRP as well as adults [36]. Values of CRP in cord blood from term infants are low, increasing to concentrations found in adult blood in the first days of life, paralleling a postnatal increase in serum IL-6 and microbial colonization [37].

MBL (similar to SP-A and SP-D described earlier) is a member of the collectin family and binds to carbohydrates, including mannose, glucose, and fucose, on the

surface of bacteria, yeasts, and some viruses [38]. When bound, MBL activates complement and enhances phagocytosis by neutrophils and macrophages. Engagement of MBL is impeded by capsular polysaccharides of most virulent bacterial pathogens. The gene encoding MBL is highly polymorphic, and as a result concentrations of MBL in healthy adults vary widely (undetectable to approximately 10 μg/mL), with approximately 40% of Europeans having low MBL and approximately 5% having little or no MBL in the blood [39,40]. MBL-deficient individuals beyond the neonatal period who are otherwise immunocompetent have a slightly higher rate of respiratory tract infections between 6 and 17 months of age, but are not otherwise predisposed to infection.

MBL abundance in neonates is affected by three interacting variables: MBL genotype, gestational age, and postnatal age. In neonates with wild-type MBL genotype, MBL concentrations are 50% to 75% of those in adults and reach adult values by 7 to 10 days of age in term neonates and 20 weeks of age in preterm neonates [41,42]. Concentrations are more than fivefold lower and these increases are less evident in neonates with variant MBL genotypes. Preterm neonates with low concentrations of MBL found in those with variant genotypes seem to be at greater risk for sepsis or pneumonia [40,42,43]. Although the rigor of the criteria by which sepsis was defined and the seriousness of the causative agent varied in these studies, it seems that neonates with values less than 0.4 μg/mL are at greater risk compared with neonates of similar gestational age or birth weight [43].

## COMPLEMENT

The complement system is composed of serum proteins that can be activated sequentially through one of three pathways—the classic, MBL, and alternative pathways—each of which leads to the generation of activated C3, C3 and C5 convertases, and the membrane attack complex (see Fig. 4–1) [44].

### Classic and Mannan-Binding Lectin Pathways

Activation of the classic pathway is initiated when antibodies capable of engaging C1q to their Fc portion (IgM, IgG1, IgG2, and IgG3 in humans) form a complex with microbial (or other) antigens. The formation of complexes alters the conformation of IgM and juxtaposes two IgG molecules, which creates an appropriate binding site for C1q. This is followed by the sequential binding of C1r and C1s to C1q. C1s can cleave C4 followed by C2, and the larger fragments of these bind covalently to the surface of the microbe or particle, forming the classic pathway C3 convertase (C2aC4b). C3 convertase cleaves C3, liberating C3b, which binds to the microbe or particle, and C3a, which is released into the fluid phase.

This pathway can also be activated before the development of antibody by CRP. When CRP binds to the surface of a microbe, its conformation is altered such that it can bind C1q and activate the classic pathway [45]. Similarly, when MBL engages the surface of a microbe, its confirmation is altered, creating a binding site for MASP1 and MASP2, which are the functional equivalents of C1r and C1s. MASP2 cleaves C4 and C2 leading to the formation of the C3 convertase.

### Alternative Pathway

The alternative pathway is activated constitutively by the continuous low-level hydrolysis of C3 in solution, creating a binding site for factor B. This complex is cleaved by factor D, generating C3b and Bb. If C3b and Bb bind to a microorganism, they form a more efficient system, which binds and activates additional C3 molecules, depositing C3b on the microbe and liberating C3a into the fluid phase. This interaction is facilitated by factor P (properdin) and inhibited by alternative pathway factors H and I. The classic pathway, by creating particle-bound C3b, also can activate the alternative pathway, amplifying complement activation. This amplification step may be particularly important in the presence of small amounts of antibody. Bacteria vary in their capacity to activate the alternative pathway, which is determined by their ability to bind C3b and to protect the complex of C3b and Bb from the inhibitory effects of factors H and I. Sialic acid, a component of many bacterial polysaccharide capsules, including those of GBS and *E. coli* K1, favors factor H binding. Many bacterial pathogens are protected from the alternative pathway by their capsules. Antibody is needed for efficient opsonization of such organisms.

### Terminal Components, Membrane Attack Complex, and Biologic Consequences of Complement Activation

Binding of C3b on the microbial surface facilitates microbial killing or removal, through the interaction of C3b with CR1 receptors on phagocytes. C3b also is cleaved to C3bi, which binds to the CR3 receptor (Mac-1, Cd11b-CD18) and CR4 receptor (CD11c-CD18). C3bi receptors are $\beta_2$ integrins, which are present on neutrophils, macrophages, and certain other cell types and play a role in leukocyte adhesion. Along with IgG antibody, which binds to Fcγ receptors on phagocytes, C3b and C3bi promote phagocytosis and killing of bacteria and fungi.

Bound C3b and C4b and C2a or bound C3b and Bb form C5 convertases, which cleave C5. The smaller fragment, C5a, is released into solution. The larger fragment, C5b, triggers the recruitment of the terminal components, C6 to C9, which together form the membrane attack complex. This complex is assembled in lipid-containing cell membranes, which include the outer membrane of gram-negative bacteria and the plasma membrane of infected host cells. When assembled in the membrane, this complex can lyse the cell. This lysis seems to be a central defense mechanism against meningococci and systemic gonococcal infection. Certain gram-negative organisms have mechanisms to impede complement-mediated lysis, and gram-positive bacteria are intrinsically resistant to complement-mediated lysis because they do not have an outer membrane. As a result, in contrast to the important role of complement-mediated opsonization, complement-mediated lysis may play a limited role in defense against common neonatal bacterial pathogens.

The soluble fragments of C5, C5a, and, to a more limited degree, C3a and C4a cause vasodilation and increase vascular permeability. C5a also is a potent chemotactic factor for phagocytes. In addition to these roles for complement in innate immunity, complement facilitates B-cell responses to T cell–dependent antigens, as discussed in the section on B cells and immunoglobulin.

## Complement in the Fetus and Neonate

Complement components are synthesized by hepatocytes and, for some components, by macrophages. Little, if any, maternal complement is transferred to the fetus. Fetal synthesis of complement components can be detected in tissues at 6 to 14 weeks of gestation, depending on the specific complement component and tissue examined [46].

Table 4–3 summarizes published reports on classic pathway complement activity ($CH_{50}$) and alternative pathway complement activity ($AP_{50}$) and individual complement components in neonates. Substantial interindividual variability is seen, and in many term neonates, values of individual complement components or of $CH_{50}$ or $AP_{50}$ are within the adult range. Alternative pathway activity and components are more consistently decreased than classic pathway activity and components. The most marked deficiency is in the terminal complement component C9, which correlates with poor killing of gram-negative bacteria by serum from neonates. The C9 deficiency in neonatal serum seems to be a more important factor in the inefficient killing of *E. coli* K1 than the deficiency in antigen-specific IgG antibodies [47]. Preterm infants show a greater and more consistent decrease in classic and alternative pathway complement activity and components [48]. Mature infants who are small for gestational age have values similar to those for healthy term infants [49]. The concentration of most complement proteins increases postnatally and reaches adult values by 6 to 18 months of age [50].

Opsonization is the process whereby soluble factors present in serum or other body fluids bind to the surface of microbes (or other particles) and enhance their phagocytosis and killing. Some organisms are effective activators of the alternative pathway, whereas others require antibody to activate complement. Depending on the organism, opsonic activity reflects antibody, MBL, CRP, classic or alternative complement pathway activity, or combinations of these, and the efficiency with which neonatal sera opsonize organisms is quite variable. Although opsonization of *S. aureus* was normal in neonatal sera in all studies [51–53], opsonization of GBS [52,54], *S. pneumoniae* [53], *E. coli* [52,55], and other gram-negative rods [52,55] was decreased against some strains and in some studies, but not in others.

Neonatal sera generally are less able to opsonize organisms in the absence of antibody. This difference is compatible with deficits in the function of the alternative and MBL pathways [56–58] and with the moderate reduction in alternative pathway components. This difference is not due to a reduced ability of neonatal sera to initiate complement activation through the alternative pathway [59]. Neonatal sera also are less able to opsonize some strains of GBS in a classic pathway–dependent but antibody-independent manner [54,60]. The deficit in antibody-independent opsonization is accentuated in sera from premature neonates and may be impaired further by the depletion of complement components in septic neonates.

Sera from term neonates generate less chemotactic activity than adult sera. This diminished activity reflects a defect in complement activation, rather than lack of antibody [61–63]. These observations notwithstanding, preterm and term neonates do generate substantial amounts of activated complement products in response to infection in vivo [64].

**TABLE 4–3** Summary of Published Complement Levels in Neonates

| Complement Component | Mean % of Adult Levels: Term Neonate | Mean % of Adult Levels: Preterm Neonate |
|---|---|---|
| $CH_{50}$ | 56-90 (5)* | 45-71 (4) |
| $AP_{50}$ | 49-65 (4) | 40-55 (3) |
| CIq | 61-90 (4) | 27-58 (3) |
| C4 | 60-100 (5) | 42-91 (4) |
| C2 | 76-100 (3) | 67-96 (2) |
| C3 | 60-100 (5) | 39-78 (4) |
| C5 | 73-75 (2) | 67 (1) |

## SUMMARY

Compared with adults, neonates have moderately diminished alternative complement pathway activity, slightly diminished classic complement pathway activity, and decreased abundance of some terminal complement components. Neonates with much reduced concentrations of MBL resulting from genetic variation and prematurity seem to be at greater risk for sepsis or pneumonia. Consistent with these findings, neonatal sera are less effective than adult sera in opsonization when concentrations of specific antibody are limiting and in the generation of complement-derived chemotactic activity; these differences are greater in preterm than in term neonates. These deficiencies, in concert with phagocyte deficits described

subsequently, may contribute to delayed inflammatory responses and impaired bacterial clearance in neonates.

# PHAGOCYTES

## HEMATOPOIESIS

Phagocytes and all leukocytes of the immune system are derived from self-renewing, pluripotent hematopoietic stem cells (HSCs), which have the capacity for indefinite self-renewal (Fig. 4–2). Most circulating HSCs in cord blood and adult bone marrow are identified by their $CD34^+CD45^+CD133^+CD143^+$ surface phenotype combined with a lack of expression of CD38 and markers found on specific lineages of mature leukocytes (e.g., they lack CD3, a T-cell marker, and are CD34 positive and lineage marker negative [$CD34^+Lin^-$]) [65,66]. HSCs are generated during ontogeny from embryonic para-aortic tissue, fetal liver, and bone marrow [67]. The yolk sac, which is extraembryonic, is a major site of production of primitive erythrocytes and some primitive mononuclear phagocytes starting at about the third week of embryonic development. HSCs that give rise to erythrocyte and all nonerythroid hematopoietic cell lineages appear in the fetal liver after 4 weeks of gestation and in the bone marrow by 11 weeks of gestation [67]. Liver-mediated hematopoiesis ceases by 20 weeks of gestation [67], with the bone marrow becoming the sole site of hematopoiesis thereafter. All major lineages of hematopoietic cells that are part of the immune system are present in the human by the beginning of the second trimester.

HSCs can subsequently differentiate into common lymphoid progenitors or common myeloid-erythroid progenitors (see Fig. 4–2). Common lymphoid progenitors give rise to T, B, and natural killer (NK) lymphocytes (discussed in later sections). Common myeloid-erythroid progenitors give rise to the megakaryocyte, erythroid, and myeloid lineages. Myeloid and lymphoid cells represent the two largely distinct but functionally interrelated immune cell lineages, with one cell type—DCs—seeming to provide a developmental and functional bridge between these lineages (see "Dendritic Cells—the Link between Innate and Adaptive Immunity").

## PHAGOCYTE PRODUCTION BY THE BONE MARROW

Phagocytes are derived from a common precursor myeloid stem cell, which often is referred to as the colony-forming unit–granulocyte-monocyte (CFU-GM) (see Fig. 4–2).

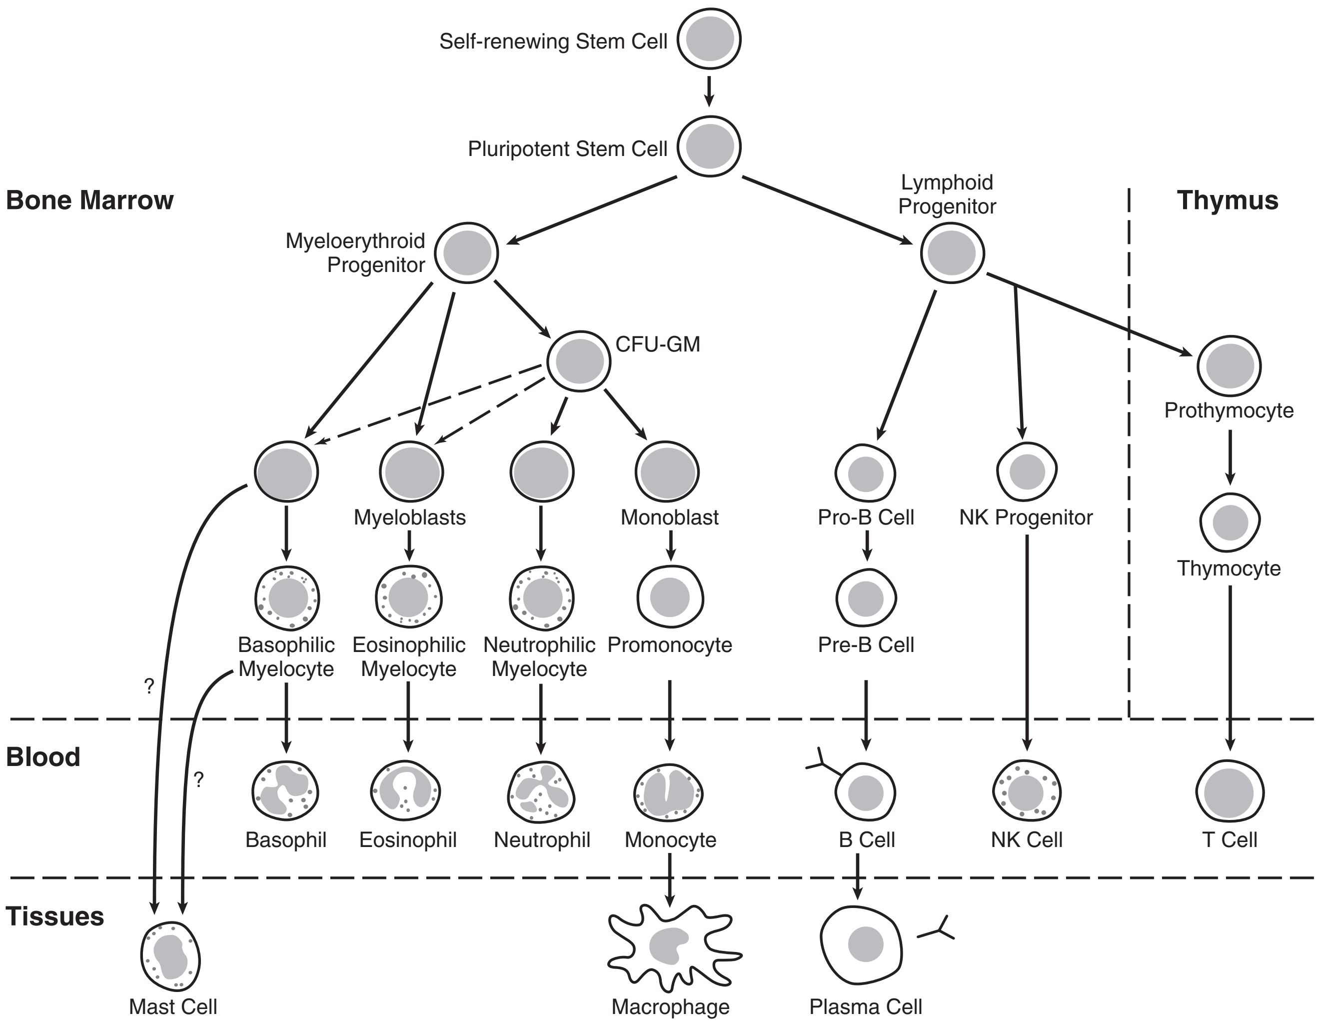

**FIGURE 4–2** Myeloid and lymphoid differentiation and tissue compartments in which they occur. CFU-GM, colony-forming unit–granulocyte-macrophage.

The formation of myeloid stem cells from pluripotent HSCs and further differentiation of the myeloid precursor into mature granulocytes and monocytes are governed by bone marrow stromal cells and soluble colony-stimulating factors (CSFs) and other cytokines (see Table 4–2) [68,69]. Factors that act primarily on early HSCs include stem cell factor (also known as steel factor or c-Kit ligand) and Flt-3 ligand. The response to these factors is enhanced by granulocyte colony-stimulating factor (G-CSF) and thrombopoietin, hematopoietic growth factors originally identified by their ability to enhance the production of neutrophils (G-CSF) and platelets (thrombopoietin). IL-3 and IL-11 augment the effects of these factors on CFU-GM. Other factors act later and are more specific for given myeloid lineages. granulocyte-macrophage colony-stimulating factor (GM-CSF) acts to increase the production of neutrophils, eosinophils, and monocytes; G-CSF acts to increase neutrophil production; macrophage colony-stimulating factor (M-CSF) acts to increase monocyte production; and IL-5 enhances eosinophil production.

The precise role of these mediators in normal steady-state hematopoiesis is becoming clearer, primarily as a result of studies in mice with targeted disruptions of the relevant genes. Genetic defects in the production of biologically active stem cell factor or its receptor c-Kit lead to mast cell deficiency and severe anemia, with less severe defects in granulocytopoiesis and in formation of megakaryocytes [70]. Deficiency for Flt-3 ligand and c-Kit has a more severe phenotype than for either alone, indicating partial redundancy in their function. Deficient production of M-CSF is associated with some diminution in macrophage numbers and a marked deficiency in maturation of osteoclasts (presumably from monocyte precursors), which results in a form of osteopetrosis [71]. Mice and humans with mutations in the G-CSF receptor are neutropenic (although they do not completely lack neutrophils) and have fewer multilineage hematopoietic progenitor cells [68]. By contrast, GM-CSF receptor deficiency does not cause neutropenia, but instead causes pulmonary alveolar proteinosis in humans and mice [72]. IL-5 deficiency results in an inability to increase the numbers of eosinophils in response to parasites or allergens. Hematopoietic growth factors apparently play complex and, in some cases, partially overlapping roles in normal steady-state production of myeloid cells.

In response to an infectious or inflammatory stimulus, the production of G-CSF and GM-CSF and certain other of these growth factors is increased, resulting in increased production and release of granulocytes and monocytes. Similarly, when given exogenously, these factors enhance production and function of the indicated cell lineages [69].

## NEUTROPHILS

### PRODUCTION

Polymorphonuclear leukocytes or granulocytes, including neutrophils, eosinophils, and basophils, are derived from CFU-GM. Neutrophils are the principal cells of interest in relation to defense against pyogenic pathogens. The first identifiable committed neutrophil precursor is the myeloblast, which sequentially matures into myelocytes, metamyelocytes, bands, and mature neutrophils. Myelocytes and more mature neutrophilic granulocytes cannot replicate and constitute the postmitotic neutrophil storage pool [73]. The postmitotic neutrophil storage pool is an important reserve because these cells can be rapidly released into the circulation in response to inflammation. Mature neutrophils enter the circulation, where they remain for approximately 8 to 10 hours and are distributed equally and dynamically between circulating cells and cells adherent to the vascular endothelium. After leaving the circulation, neutrophils do not recirculate and die after approximately 24 hours. Release of neutrophils from the marrow may be enhanced in part by cytokines, including IL-1, IL-17 and TNF-α, in response to infection or inflammation [74,75].

Neutrophil precursors are detected at the end of the first trimester, appearing later than macrophage precursors [76]. Mature neutrophils are first detected by 14 to 16 weeks of gestation, but at mid-gestation the numbers of postmitotic neutrophils in the fetal liver and bone marrow remain markedly lower than in term newborns and adults [77]. By term, the numbers of circulating neutrophil precursors are 10-fold to 20-fold higher in the fetus and neonate than in the adult, and neonatal bone marrow also contains an abundance of neutrophil precursors [78,79]. The rate of proliferation of neutrophil precursors in the human neonate seems to be near maximal [78,80], however, suggesting that the capacity to increase numbers in response to infection may be limited.

At birth, neutrophil counts are lower in preterm than in term neonates and in neonates born by cesarean section without labor. Within hours of birth, the numbers of circulating neutrophils increase sharply [81–83]. The number of neutrophils normally peaks shortly thereafter, whereas the fraction of neutrophils that are immature (bands and less mature forms) remains constant at about 15%. Peak counts occur at approximately 8 hours in neonates greater than 28 weeks' gestation and at approximately 24 hours in neonates less than 28 weeks' gestation, then decline to a stable level by approximately 72 hours in neonates without complications. Thereafter, the lower limit of normal for term and preterm neonates is approximately 2500/μL and 1000/μL; the upper limit of normal is approximately 7000/μL for term and preterm neonates under most conditions, but may be higher (approximately 13,000/μL) for neonates living at higher altitudes, as observed in neonates living at approximately 1500 m elevation in Utah [83].

Values may be influenced by numerous additional factors. Most important is the response to sepsis. Septic infants may have normal or increased neutrophil counts. Sepsis and other perinatal complications, including maternal hypertension, periventricular hemorrhage, and severe asphyxia, can cause neutropenia, however, and severe or fatal sepsis often is associated with persistent neutropenia, particularly in preterm neonates [78,84,85]. Neutropenia may be associated with increased margination of circulating neutrophils, which occurs early in response to infection [73]. Neutropenia that is sustained often reflects depletion of the neonate's limited postmitotic neutrophil storage pool. Septic neutropenic neonates

in whom the neutrophil storage pool is depleted are more likely to die than neonates with normal neutrophil storage pools [85]. Leukemoid reactions also are observed at a frequency of approximately 1% in term neonates in the absence of an identifiable cause. Such reactions apparently reflect increased neutrophil production [86].

Circulating G-CSF levels in healthy infants are highest in the first hours after birth, and levels in premature neonates are generally higher than levels in term neonates [87–89]. Levels decline rapidly in the neonatal period and more slowly thereafter. One study reported a direct correlation between circulating levels of G-CSF and the blood absolute neutrophil count, although this finding has not been confirmed in other studies [87,88]. Plasma G-CSF levels tend to be elevated in neonates with infection [89], although some studies have found considerable overlap with the levels of neonates without infection [90]. Although the cause of neutropenia in these neonates was not described, these observations raise the possibility that deficient G-CSF production might be a contributory factor to neutropenia in some neonates. Mononuclear cells and monocytes from mid-gestation fetuses and premature neonates generally produce less G-CSF and GM-CSF after stimulation in vitro than comparable adult cell types, whereas cells from term neonates produce amounts that are similar to or modestly less than amounts produced by cells of adults [91–95].

## MIGRATION TO SITES OF INFECTION OR INJURY

After release from the bone marrow into the blood, neutrophils circulate until they are called on to enter infected or injured tissues. Neutrophils adhere selectively to endothelium in such tissues, but not in normal tissues. The adhesion and subsequent migration of neutrophils through blood vessels into tissues and to the site of infection results from a multistep process, which is governed by the pattern of expression on their surface of adhesion molecules and receptors for chemotactic factors and by the local patterns and gradients of adhesion molecule and chemotactic factors in the tissues.

The adhesion molecules involved in neutrophil migration from the blood into tissues include selectins, integrins, and the molecules to which they adhere (Table 4–4) [96]. The selectins are named by the cell types in which they are primarily expressed: L-selectin by leukocytes, E-selectin by endothelial cells, and P-selectin by platelets and endothelial cells. L-selectin is constitutively expressed on leukocytes and seems to bind to tissue-specific or inflammation-specific, carbohydrate-containing ligands on endothelial cells. E-selectin and P-selectin are expressed on activated, not resting, endothelial cells or platelets. E-selectin and P-selectin bind to sialylated glycoproteins on the surface of leukocytes, including P-selectin

**TABLE 4–4** Selected Pairs of Surface Molecules Involved in T Cell–Antigen-Presenting Cell (APC) Interactions

| T Cell Surface Molecule | T Cell Distribution | Corresponding Ligands on APCs | APC Distribution |
|---|---|---|---|
| CD2 | Most T cells; higher on memory cells, lower on adult naïve and neonatal T cells | LFA-3 (CD58), CD59 | Leukocytes |
| CD4 | Subset of αβ T cells with predominantly helper activity | MHC class II β chain | Dendritic cells, Mϕ, B cells, others (see text) |
| CD5 | All T cells | CD72 | B cells, Mϕ |
| CD8 | Subset of αβ T cells with predominantly cytotoxic activity | MHC glass I heavy chain | Ubiquitous |
| LFA-1 (CD11a/CD18) | All T cells; higher on memory cells, lower on adult naïve and neonatal T cells | ICAM-1 (CD54) | Leukocytes (ICAM-3 > ICAM-1, ICAM-2) and endothelium (ICAM-1, ICAM-2); most ICAM-1 expression requires activation |
| | | ICAM-2 (CD102) | |
| | | ICAM-3 (CD50) | |
| CD28 | Most $CD4^+$ T cells, subset of $CD8^+$ T cells | CD80 (B7-1) | Dendritic cells, Mϕ, activated B cells |
| | | CD86 (B7-2) | |
| ICOS | Effector and memory T cells; not on resting naïve cells | B7RP-1 (B7h) | B cells, Mϕ, dendritic cells, endothelial cells |
| VLA-4 (CD49d/CD29) | All T cells; higher on memory cells, lower on adult naïve and neonatal T cells | VCAM-1 (CD106) | Activated or inflamed endothelium (increased by TNF, IL-1, IL-4) |
| ICAM-1 (CD54) | All T cells; higher on memory cells, lower on adult virgin and neonatal T cells | LFA-1 (CD11a/CD18) | Leukocytes |
| CTLA-4 (CD152) | Activated T cells | CD80 | Dendritic cells, Mϕ, activated B cells, activated T cells |
| | | CD86 | |
| CD40 ligand (CD154) | Activated $CD4^+$ T cells; lower on neonatal $CD4^+$ T cells | CD40 | Dendritic cells, Mϕ, B cells, thymic epithelial cells |
| PD-1 | Activated $CD4^+$ and $CD8^+$ T cells | PD-L1, PD-L2 | Dendritic cells, Mϕ, B cells, regulatory T cells |

*CTLA-4, cytotoxic T-lymphocyte antigen-4; ICAM, intercellular adhesion molecule; ICOS, inducible costimulator; IL, interleukin; LFA, leukocyte function antigen; Mϕ, mononuclear phagocytes; MHC, major histocompatibility complex; PD, programmed death [molecule]; VCAM, vascular cell adhesion molecule; VLA-4, very late antigen-4.*

glycoprotein ligand-1. L-selectin binds to glycoproteins and glycolipids, which are expressed on vascular endothelial cells in specific tissues. The integrins are a large family of heterodimeric proteins composed of an α and a β chain. $\beta_2$ integrins LFA-1 (CD11a through CD18) and Mac-1 (CD11b through CD18) play a crucial role in neutrophil function because neutrophils do not express other integrins in substantial amounts. $\beta_2$ integrins are constitutively expressed on neutrophils, but their abundance and avidity for their endothelial ligands are increased after activation of neutrophils in response to chemotactic factors. Their endothelial ligands include intercellular adhesion molecule (ICAM)-1 and ICAM-2. Both are constitutively expressed on endothelium, but ICAM-1 expression is increased markedly by exposure to inflammatory mediators, including IL-1, TNF-α, and LPS.

Chemotactic factors may be derived directly from bacterial components, such as n-formylated-Met-Leu-Phe (fMLP) peptide; from activated complement, including C5a; and from host cell lipids, including leukotriene $B_4$ ($LTB_4$) [97]. In addition, a large family of chemotactic cytokines (chemokines) are synthesized by macrophages and many other cell types (see Tables 4–1 and 4–2). Chemokines constitute a cytokine superfamily with more than 50 members known at present, most of which are secreted and of relatively low molecular weight [98]. Chemokines attract various leukocyte populations, which bear the appropriate G protein–linked chemokine receptors. They can be divided into four families according to their pattern of amino-terminal cysteine residues: CC, CXC, C, and CX3C (X represents a noncysteine amino acid between the cysteines).

A nomenclature for the chemokines and their receptors has been adopted, in which the family is first denoted (e.g., CC), followed by L for ligand (the chemokine itself) and a number or followed by R (for receptor) and a number. Functionally, chemokines also can be defined by their principal function—in homeostatic or inflammatory cell migration—and by the subsets of cells on which they act. Neutrophils are attracted by the subset of CXC chemokines that contain a glutamine-leucine-arginine motif, including the prototypic neutrophil chemokine CXLC8, also known as IL-8.

These adhesion molecules and chemotactic factors act in a coordinated fashion to allow neutrophil recruitment. In response to injury or inflammatory cytokines, E-selectin and P-selectin are expressed on the endothelium of capillaries or postcapillary venules. Neutrophils in the blood adhere to these selectins in a low-avidity fashion, allowing them to roll along the vessel walls. This step is transient and reversible, unless a second, high-avidity interaction is triggered. At the time of the low-avidity binding, if neutrophils also encounter chemotactic factors released from the tissues or from the endothelium itself, they rapidly upregulate the avidity and abundance of LFA-1 and Mac-1 on the neutrophil cell surface. This process results in high-avidity binding of neutrophils to endothelial cells, which, in the presence of a gradient of chemotactic factors from the tissue to the blood vessel, induces neutrophils to migrate across the endothelium and into the tissues. Neutrophils must undergo considerable deformation to allow diapedesis through the endothelium. Migration through the tissues also is likely to be facilitated by the reversible adhesion and deadhesion between ligands on the neutrophil surface, including the integrins, and components of the extracellular matrix, such as fibronectin and collagen.

The profound importance of integrin-mediated and selectin-mediated leukocyte adhesion is illustrated by the genetic leukocyte adhesion deficiency syndromes [99]. Deficiency of the common $\beta_2$ integrin chain results in inability of leukocytes to exit the bloodstream and reach sites of infection and injury in the tissues. Affected patients are profoundly susceptible to infections with pathogenic and nonpathogenic bacteria and may present in early infancy with delayed separation of the umbilical cord, omphalitis, and severe bacterial infection without pus formation. A related syndrome—leukocyte adhesion deficiency syndrome type II—is due to a defect in synthesis of the carbohydrate selectin ligands.

## MIGRATION OF NEONATAL NEUTROPHILS

The ability of neonatal neutrophils to migrate from the blood into sites of infection and inflammation is reduced or delayed, and the transition from a neutrophilic to mononuclear cell inflammatory response is delayed [76]. This diminished delivery of neutrophils may result in part from defects in adhesion and chemotaxis.

Adhesion of neonatal neutrophils under resting conditions is normal or at most modestly impaired, whereas adhesion of activated cells is deficient [100,101]. Adhesion and rolling of neonatal neutrophils to activated endothelium under conditions of flow similar to those found in capillaries or postcapillary venules is variable, but on average approximately 50% of that observed with adult neutrophils [102,103]. This decreased adhesion seems to reflect, at least in part, decreased abundance and shedding of L-selectin and decreased binding of neonatal neutrophils to P-selectin [102,103]. Resting neonatal and adult neutrophils have similar amounts of Mac-1 and LFA-1 on their plasma membrane, but neonatal neutrophils have a reduced ability to upregulate expression of these integrins after exposure to chemotactic agents [102–104]. Reduced integrin upregulation is associated with a parallel decrease in adhesion to activated endothelium or ICAM-1 [105]. Two studies have concluded, however, that expression of Mac-1 and LFA-1 is not reduced on neonatal neutrophils, and that diminished expression observed in other studies may be an artifact of the methods used to purify neutrophils [106,107]. Nonetheless, the preponderance of data suggests that a deficit in adhesion underlies in part the diminished ability of neonatal neutrophils to migrate through endothelium into tissues, and these defects are greater in preterm neonates [102,105].

In nearly all studies in which neutrophil migration has been examined in vitro, chemotaxis of neonatal neutrophils was less than that of adult neutrophils. Some studies have found that chemotaxis remains less than that of adult cells until 1 to 2 years of age, whereas others have suggested more rapid maturation [61,108]. The response of neonatal neutrophils to various chemotactic factors, such as fMLP, $LTB_4$, and neutrophil-specific chemokines

including IL-8, is reduced [109–111]. Chemotactic factor binding and dose response patterns of neonatal neutrophils seem to be similar to adult neutrophils, whereas downstream processes, including expression of Rac2, increases in free intracellular calcium concentration ($[Ca^{2+}]_i$) and inositol phospholipid generation, and change in cell membrane potential, are impaired [112–114]. An additional factor may be the reduced deformability of neonatal neutrophils, which may limit their ability to enter the tissues after binding to the vascular endothelium [101,115]. Decreased generation of chemotactic factors in neonatal serum [61,116] may compound the intrinsic chemotactic deficits of neonatal neutrophils. The generation of other chemotactic agents, such as $LTB_4$, by neonatal neutrophils seems to be normal, however [117]. It has also been hypothesized that the relatively greater production by neonatal phagocytes and DCs of the cytokine IL-6 (see later), which impedes neutrophil migration into tissues, may dampen neutrophil recruitment [118], but this notion has not been tested.

## PHAGOCYTOSIS

Having reached the site of infection, neutrophils must bind, phagocytose, and kill the pathogen [119]. Opsonization greatly facilitates this process. Neutrophils express on their surface receptors for multiple opsonins, including receptors for the Fc portion of the IgG molecule (Fcγ receptors)—FcγRI (CD64), FcγRII (CD32), and FcγRIII (CD16) [120]. Neutrophils also express receptors for activated complement components C3b and C3bi [121], which are bound by CR1, CR3 (CD11b-CD18) and CR4 (CD11c-CD18). Opsonized bacteria bind and cross-link Fcγ and C3b-C3bi receptors. This cross-linkage transmits a signal for ingestion and for the activation of the cell's microbicidal mechanisms.

Under optimal in vitro conditions, neutrophils from healthy neonates bind and ingest gram-positive and gram-negative bacteria as well as or only slightly less efficiently than adult neutrophils [115,122,123]. The concentrations of opsonins are reduced in serum from neonates, in particular preterm neonates, however, and when concentrations of opsonins are limited [51], neutrophils from neonates ingest bacteria less efficiently than neutrophils from adults. Consistent with this finding, phagocytosis of bacteria by neutrophils from preterm, but not term, neonates is reduced compared with adult neutrophils when assayed in whole blood [124–126]. Why neonatal neutrophils have impaired phagocytosis when concentrations of opsonins are limiting is incompletely understood. Basal expression of receptors for opsonized bacteria is not greatly different. Neutrophils from neonates, particularly preterm neonates, express greater amounts of the high-affinity FcγRI, lesser amounts of FcγRIII, and similar or slightly reduced amounts of FcγRII at birth compared with adults; values in preterm neonates approach values of term neonates by 1 month of age [127]. Expression of complement receptors on neutrophils from term neonates and adults is similar, but reduced expression of CR3 on neutrophils from preterm neonates has been reported in some studies [107,127]. Neutrophils from preterm neonates also are less able to upregulate CR3 in response to LPS and chemotactic factors [128–130]. Lower expression of proteins involved in the engulfment process, including Rac2 as noted earlier, may also contribute to impaired phagocytosis when concentrations of opsonins are limited.

## KILLING

After ingestion, neutrophils kill ingested microbes through oxygen-dependent and oxygen-independent mechanisms. Oxygen-dependent microbicidal mechanisms are of central importance, as illustrated by the severe compromise in defenses against a wide range of pyogenic pathogens (with the exception of catalase-negative bacteria) observed in children with a genetic defect in this system [131]. Children with this disorder have a defect in one of several proteins that constitute the phagocyte oxidase, which is activated during receptor-mediated phagocytosis. The assembly of the oxidase in the plasma membrane results in the generation and delivery of reactive oxygen metabolites, including superoxide anion, hydrogen peroxide, and hydroxyl radicals. These oxygen radicals along with the granule protein myeloperoxidase are discharged into the phagocytic vacuole, where they collaborate in killing ingested microbes. In addition to this oxygen-dependent pathway, neutrophils contain other granule proteins with potent microbicidal activity, including the defensins HNP1 through HNP4, the cathelicidin LL-37, elastase, cathepsin G, and bactericidal permeability-increasing protein, a protein that binds selectively to and helps to kill gram-negative bacteria [1,132–134].

Oxygen-dependent and oxygen-independent microbicidal mechanisms of neonatal and adult neutrophils do not differ greatly [115,123]. Generation of superoxide anion and hydrogen peroxide by neutrophils from term neonates is generally similar to or greater than that by adult cells in response to soluble stimuli [135,136]. Although a modest reduction in the generation of reactive oxygen metabolites by neutrophils from preterm compared with term neonates was seen in response to some strains of coagulase-negative staphylococci, this was not observed with other strains or with a strain of GBS and is of uncertain significance [137]. By contrast, LPS primes adult neutrophils for increased production of reactive oxygen metabolites, but priming is much reduced with neonatal neutrophils, which could limit their efficacy in response to infection in vivo [130,138]. Studies of oxygen-independent microbicidal mechanisms of neonatal neutrophils are less complete. Compared with adult neutrophils, neonatal neutrophils contain and release reduced amounts of bactericidal permeability-increasing protein (approximately twofold to threefold) and lactoferrin (approximately twofold), but contain or release comparable amounts of myeloperoxidase, defensins, and lysozyme [115,123,139,140].

Consistent with these findings, killing of ingested gram-positive and gram-negative bacteria and *Candida* organisms by neutrophils from neonates and adults is generally similar [115,123]. Variable and usually mildly decreased bactericidal activity has been noted, however, against *P. aeruginosa* [141], *S. aureus* [142], and certain strains of GBS [143–145]. Deficits in killing of engulfed

microbes by neonatal neutrophils are more apparent at high ratios of bacteria to neutrophils [146], as is killing by neutrophils from sick or stressed neonates (i.e., neonates born prematurely or who have sepsis, respiratory impairment, hyperbilirubinemia, premature rupture of membranes, or hypoglycemia) [147,148]. Whether killing by neonatal than adult neutrophils is more severely compromised by comparable illnesses is uncertain, however.

### NEUTROPHIL CLEARANCE AND RESOLUTION OF NEUTROPHILIC INFLAMMATION

Neutrophils undergo apoptosis 1 to 2 days after egress from the bone marrow and are efficiently cleared by tissue macrophages without producing inflammation or injury. In the context of infection or sterile inflammation, their survival is prolonged by colony-stimulating factors and other inflammatory mediators, allowing them to aid in microbial clearance, while augmenting or perpetuating tissue injury. Studies from several groups have shown that spontaneous and anti-Fas–induced apoptosis of isolated neonatal neutrophils is reduced when these cells are cultured in vitro [76,149–151], although this was not observed in one study in which neutrophil survival in whole blood for a shorter time was assessed [152]. The greater survival of neonatal than adult neutrophils was associated with reduced expression of the apoptosis-inducing Fas receptor and proapoptotic members of the Bcl-2 family, but whether these differences account for the greater survival is uncertain [149]. The increased survival of neonatal neutrophils has led some authorities to speculate that this may help to compensate for the neonate's limited neutrophil storage pool in protection against infection, but also contributes to persistent untoward inflammation and tissue injury [76].

### EFFECTS OF IMMUNOMODULATORS

After systemic treatment with G-CSF and GM-CSF, the number of neutrophils increases in neonates, as does expression of CR3 on these cells [80]. The increased numbers likely reflect increased production and survival [149,151]. GM-CSF and interferon (IFN)-$\gamma$ enhance the chemotactic response of neonatal neutrophils [80,153], although at high concentrations GM-CSF inhibits chemotaxis, while augmenting oxygen radical production [154]. The methylxanthine pentoxifylline exhibits a biphasic enhancement of chemotaxis by neonatal neutrophils [115]. Of potential concern, indomethacin, which is used clinically to facilitate ductal closure in premature neonates, impairs chemotaxis of cells from term and preterm neonates [155].

### SUMMARY

The most critical deficiency in phagocyte defenses in the term and particularly preterm neonate is the limited ability to accelerate neutrophil production in response to infection. This age-specific limitation seems to result in large part from a limited neutrophil storage pool and perhaps a more limited ability to increase neutrophil production in response to infection. Impaired migration of neutrophils into tissues is likely also to be a factor, whereas phagocytosis and killing do not seem to be greatly impaired. Persistent inflammation and tissue injury may result from impaired clearance of infection and protracted neutrophilic inflammation after the infection is cleared.

## EOSINOPHILS

In adults and older children, eosinophils represent a small percentage of the circulating granulocytes. In the healthy fetus and neonate, eosinophils commonly represent a larger percentage (10% to 20%) of total granulocytes than in adults [156,157]. Numbers of eosinophils increase postnatally, peaking at 3 to 4 weeks of postnatal life. A relative increase in the abundance of eosinophils in inflammatory exudates of various causes is also seen in neonates, paralleling their greater numbers in the circulation [103]. Eosinophil-rich inflammatory exudates do not suggest the presence of allergic disease or helminth infection as strongly as they do in older individuals. The degree of eosinophilia is greater yet in preterm neonates and in neonates with Rh disease, total parenteral nutrition, and transfusions [158]. This physiologic neonatal eosinophilia is not associated with increased amounts of circulating IgE [159]. The basis for the eosinophilic tendency of the neonate is unknown. By contrast to the diminished migration of neonatal neutrophils, neonatal eosinophils exhibit greater spontaneous and chemotactic factor–induced migration than adult eosinophils [157]. Their greater numbers and ability to migrate may contribute to the relatively greater abundance of eosinophils in neonatal inflammatory infiltrates, including those seen in physiologic conditions such as erythema toxicum (see "Epithelial Barriers").

## MONONUCLEAR PHAGOCYTES

### PRODUCTION AND DIFFERENTIATION OF MONOCYTES AND RESIDENT TISSUE MACROPHAGES

Together, monocytes and tissue macrophages are referred to as mononuclear phagocytes. Blood monocytes are derived from bone marrow precursors (monoblasts and promonocytes). Under steady-state conditions, monocytes are released from the bone marrow within 24 hours and circulate in the blood for 1 to 3 days before moving to the tissues [160], where they differentiate into tissue macrophages or conventional DCs (cDCs). All monocytes express CD14, which serves as a coreceptor for recognition of LPS by TLR4/MD-2. CD14 is commonly used as a lineage marker for these cells because they are the only cell type that expresses it in high amounts. Monocytes also express the human leukocyte antigen (HLA) HLA-DR and can present antigens to CD4 T cells, although the amounts expressed and efficiency of antigen presentation are less than by DCs. Monocytes are heterogeneous. A small subset (approximately 10% in adults) of monocytes expresses CD16 (Fc$\gamma$RIII). This monocyte subset expresses more of the surface major histocompatibility complex (MHC) class II molecule HLA-DR (MHC

molecules and their functions are discussed subsequently in “Antigen Presentation by Classic Major Histocompatibility Complex Molecules”), produces greater amounts of proinflammatory cytokines, and more readily differentiates into DCs after entry into tissues than the CD16-negative subset [161].

Macrophages are resident in tissues throughout the body, where they have multiple functions, including the clearance of dead host cells, phagocytosis and killing of microbes, secretion of inflammatory mediators, and presentation of antigen to T cells. The functions of macrophages are readily modulated by cytokines, and macrophages can fuse to form multinucleated giant cells. The estimated life span of macrophages in the tissues is 4 to 12 weeks, and they are capable of limited replication in situ [162,163].

Macrophages are detectable by 4 weeks of fetal life in the yolk sac and are found shortly thereafter in the liver and then in the bone marrow [164]. The capacity of the fetus and the neonate to produce monocytes is at least as great as that of adults [165]. The numbers of monocytes per volume of blood in neonates are equal to or greater than the numbers in adults [166]. Neonatal blood monocytes express approximately 50% as much HLA-DR as adult monocytes, and a larger fraction of neonatal monocytes lack detectable HLA-DR [161]. A similar fraction of neonatal, infant, and adult monocytes are $CD16^{+}$, so the diminished expression of HLA-DR cannot be attributed to the absence of this subset.

The numbers of tissue macrophages in human neonates are less well characterized. Limited data in humans, which are consistent with data in various animal species, suggest that the lung contains few macrophages until shortly before term [167]. Postnatally, the numbers of lung macrophages increase to adult levels by 24 to 48 hours in healthy monkeys [168]. A similar increase occurs in humans, although the data are less complete and by necessity derived from individuals with clinical problems necessitating tracheobronchial lavage [169]. The blood of premature neonates contains increased numbers of pitted erythrocytes or erythrocytes containing Howell-Jolly bodies [170], suggesting that the ability of splenic and liver macrophages to clear these effete cells, and perhaps microbial cells, may be reduced in the fetus and premature infant.

## MIGRATION TO SITES OF INFECTION AND DELAYED HYPERSENSITIVITY RESPONSES

Similar to neutrophils, mononuclear phagocytes express the adhesion molecules L-selectin and $\beta_2$ integrins. These cells also express substantial amounts of the $\alpha_4\beta_1$ integrin (VLA-4), allowing them, in contrast to neutrophils, to adhere efficiently to endothelium expressing vascular cell adhesion molecule (VCAM)-1, the ligand for VLA-4 [171]. Interaction of VLA-4 with VCAM-1 allows monocytes to enter tissues in states in which there is little or no neutrophilic inflammation. As in neutrophils, monocyte chemotaxis, integrin avidity, and strength of vascular adhesion are regulated by chemotactic factors, including fMLP, C5a, $LTB_4$, and chemokines. Chemokines that are chemotactic for neutrophils are not generally chemotactic for monocytes, and vice versa. Monocytes respond to a range of CC chemokines, such as CCL2 (MCP-1) [98].

The acute inflammatory response is characterized by an initial infiltration of neutrophils that is followed within 6 to 12 hours by the influx of mononuclear phagocytes [160]. The orchestration of this sequential influx of leukocytes seems to be governed by the temporal order in which specific inflammatory cytokines, chemokines, and endothelial adhesins are expressed, with some data suggesting an important role for IL-6 in this transition [172]. Some inflammatory responses, including delayed-type hypersensitivity (DTH) reactions induced by the injection of antigens (e.g., purified protein derivative [PPD]) to which the individual is immune (i.e., has developed an antigen-specific T-cell response), are characterized by the influx of mononuclear phagocytes and lymphocytes with very minimal or no initial neutrophilic phase [173].

The influx of monocytes into sites of inflammation, including DTH responses, is delayed and attenuated in neonates compared with adults [174–176]. This is true even when antigen-specific T-cell responses are evident in vitro, suggesting that decreased migration of monocytes and lymphocytes into the tissues is responsible for the poor response in neonates. Whether this delay results from impaired chemotaxis of neonatal monocytes or impaired generation of chemotactic factors or both is unresolved [61,62,108,177].

## ANTIMICROBIAL PROPERTIES OF MONOCYTES AND MACROPHAGES

Although neutrophils ingest and kill pyogenic bacteria more efficiently, resident macrophages are the initial line of phagocyte defense against microbial invasion in the tissues. When the microbial insult is modest, these cells are sufficient. If not, they produce cytokines and other inflammatory mediators to direct the recruitment of circulating neutrophils and monocytes from the blood. Monocytes and macrophages express receptors that bind to microbes, including Fc$\gamma$RI, Fc$\gamma$RII, and Fc$\gamma$RIII that bind IgG-coated microbes[120]; Fc$\alpha$R that binds IgA-coated microbes[178]; and CR1 and CR3 receptors that bind microbes coated with C3b and C3bi [179]. Microbes bound through these receptors are efficiently engulfed by macrophages and when ingested can be killed by microbicidal mechanisms, including many of the mechanisms also employed by neutrophils and discussed in the preceding section. Mononuclear phagocytes generate reactive oxygen metabolites, but in lesser amounts than neutrophils. Circulating monocytes, but not tissue macrophages, contain myeloperoxidase, which facilitates the microbicidal activity of hydrogen peroxide. The expression of microbicidal granule proteins differs in mononuclear phagocytes and neutrophils; for example, human mononuclear phagocytes express $\beta$-defensins, but not $\alpha$-defensins [180].

The microbicidal activity of resident tissue macrophages is relatively modest. This limited activity may be important in allowing macrophages to remove dead or damaged host cells and small numbers of microbes without excessively damaging host tissues. In response to

infection, macrophage microbicidal and proinflammatory functions are enhanced in a process referred to as macrophage activation [123,181]. Macrophage activation results from the integration of signals from TLRs and other innate immune pattern recognition receptors (discussed later) and receptors for activated complement components, immune complexes, cytokines, and ligands produced by other immune cells, including IFN-γ, CD40 ligand, TNF-α and GM-CSF [181,182].

The increased antimicrobial activity of activated macrophages results in part from increased expression of FcγRI, enhanced phagocytic activity, and increased production of reactive oxygen metabolites. Other antimicrobial mechanisms induced by activation of these cells include the catabolism of tryptophan by indoleamine 2,3-dioxygenase, scavenging of iron, and production of nitric oxide and its metabolites by inducible nitric oxide synthase. The last is a major mechanism by which activated murine macrophages inhibit or kill various intracellular pathogens. The role of nitric oxide in the antimicrobial activity of human macrophages is controversial, however. Activated mononuclear phagocytes also secrete numerous noncytokine products that are potentially important in host defense mechanisms. These include complement components, fibronectin, and lysozyme.

Activation of macrophages plays a crucial role in defense against infection with intracellular bacterial and protozoan pathogens that replicate within phagocytic vacuoles. Support for this notion comes from studies in humans and mice with genetic deficiencies that impair the activation of macrophages by IFN-γ. Humans with genetic defects involving IL-12, which induces IFN-γ production by NK and T cells; the IL-12 receptor; the IFN-γ receptor; or the transcription factor STAT-1, which is activated via the IFN-γ receptor, experience excessive infections with mycobacteria and *Salmonella* [39]. Deficiency of TNF-α or its receptors in mice and treatment of humans with antagonists of TNF-α also impair antimycobacterial defenses [183,184]. Patients with the X-linked hyper-IgM syndrome, which is due to a defect in CD40 ligand, are predisposed to disease caused by *Pneumocystis jiroveci* and *Cryptosporidium parvum*, in addition to the problems they experience from defects in antibody production (see section on T-cell help for antibody production) [185]. These findings are consistent with the notion that IFN-γ–mediated, TNF-α–mediated, and CD40 ligand–mediated macrophage activation is important in host defense against these pathogens, and that these molecules activate macrophages, at least in part, in a nonredundant manner.

By contrast to this canonical pathway of macrophage activation, macrophages exposed to cytokines produced by T helper type 2 ($T_H2$) cells, which are induced by infection with parasitic helminths, are activated in an alternative manner [181]. These alternatively activated macrophages dampen acute inflammation, impede the generation of reactive nitrogen products, attenuate proinflammatory T-cell responses, and foster fibrosis through the production of arginase and other mediators. Although best characterized in mice, this alternative pathway is likely to be relevant in humans as well.

## ANTIMICROBIAL ACTIVITY AND ACTIVATION OF NEONATAL MONOCYTES AND MACROPHAGES

Monocytes from human neonates and adults ingest and kill *S. aureus*, *E. coli*, and GBS with similar efficiency [143,177,186–188]. Consistent with these findings, the production of microbicidal oxygen metabolites by neonatal and adult monocytes is similar [187,189–192]. Neonatal and adult monocytes, monocyte-derived macrophages, and fetal macrophages are comparable in their ability to prevent herpes simplex virus (HSV) from replicating within them [193,194]. Although neonatal monocytes may be slightly less capable of killing HSV-infected cells than adult monocytes in the absence of antibody, they are equivalent in the presence of antibody [195,196].

The ability of neonatal and adult monocyte-derived macrophages (monocytes cultured in vitro) to phagocytose GBS, other bacteria, and *Candida* through receptors for mannose and fucose, IgG, and complement components is similar. Despite comparable phagocytosis, neonatal monocyte-derived macrophages kill *Candida* and GBS less efficiently. GM-CSF, but not IFN-γ, activates neonatal monocyte-derived macrophages to produce superoxide anion and to kill these organisms, whereas both of these cytokines activate adult macrophages [197–199]. The lack of response to IFN-γ by neonatal macrophages was associated with normal binding to its receptor, but decreased activation of STAT-1 [197]. Macrophages obtained from aspirated bronchial fluid of neonates were found to be less effective at killing the yeast form of *C. albicans* than bronchoalveolar macrophages from adults [200]. To our knowledge, this result has not been reproduced, and the decreased effectiveness could reflect differences in the source of cells. Nonetheless, similar studies with alveolar macrophages from newborn and particularly premature newborn monkeys, rabbits, and rats also have shown reduced phagocytic or microbicidal activity [201–206]. In contrast to these reports of decreased antimicrobial activity and failure of macrophage activation by IFN-γ, blood monocytes and IFN-γ–treated monocyte-derived and placental macrophages from neonates kill and restrict the growth of *Toxoplasma gondii* as effectively as cells from adults [207,208].

## MONONUCLEAR PHAGOCYTES PRODUCE CYTOKINES AND OTHER MEDIATORS THAT REGULATE INFLAMMATION AND IMMUNITY

Monocytes and macrophages produce cytokines, chemokines, colony-stimulating factors, and other mediators in response to ligand binding by TLRs and other pattern recognition receptors expressed by these cells (described in the next section), by cytokines produced by other cell types, by activated complement components and other mediators, and by engagement of CD40 on their surface by CD40 ligand expressed on activated helper T cells [181,182]. These include the cytokines IL-1, TNF-α, IL-6, and α and β IFNs (type I IFNs), which induce the production of prostaglandin $E_2$, which induces fever [209,210], accounting for the antipyretic effect of drugs that inhibit prostaglandin synthesis. Fever may have a

beneficial role in host resistance to infection by inhibiting the growth of certain microorganisms and by enhancing host immune responses [211]. TNF-α, IL-1, IL-6, and type I IFNs also act on the liver to induce the acute-phase response, which is associated with decreased albumin synthesis and increased synthesis of certain complement components, fibrinogen, CRP, and MBL. G-CSF, GM-CSF, and M-CSF enhance the production of their respective target cell populations, increasing the numbers of phagocytes available.

At sites of infection or injury, TNF-α and IL-1 increase endothelial cell expression of adhesion molecules, including E-selectin, P-selectin, ICAM-1, and VCAM-1; increase endothelial cell procoagulant activity; and enhance neutrophil adhesiveness by upregulating $\beta_2$ integrin expression [96]. IL-6 may help to terminate neutrophil recruitment into tissues and to facilitate a switch from an inflammatory infiltrate rich in neutrophils to one dominated by monocytes and lymphocytes [172]. IL-8 and other related CXC chemokines that share with IL-8 an N-terminal glu-leu-arg motif enhance the avidity of neutrophil $\beta_2$ integrins for ICAM-1 and attract neutrophils into the inflammatory-infectious focus; CC chemokines play a similar role in attracting mononuclear phagocytes and lymphocytes. These and additional factors contribute to edema, redness, and leukocyte infiltration, which characterize inflammation.

In addition to secreting cytokines that regulate the acute inflammatory response and play a crucial role in host defense to extracellular bacterial and fungal pathogens, monocytes and macrophages (and DCs—see later) produce cytokines that mediate and regulate defense against intracellular viral, bacterial, and protozoan pathogens. Type I IFNs directly inhibit viral replication in host cells [212,213], as do IFN-γ and TNF-α [214]. IL-12, IL-23, and IL-27 are members of a family of heterodimeric cytokines that help to regulate T-cell and NK-cell differentiation and function [215]. IL-12 is composed of IL-12/23 p40 and p35, IL-23 is composed of IL-12/23 p40 and p19, and IL-27 is composed of EBI-3 and p28 [215,216]. IL-12, in concert with IL-15 and IL-18 [217,218], enhances NK-cell lytic function and production of IFN-γ and facilitates the development of CD4 T helper type 1 ($T_H1$) and CD8 effector T cells, which are discussed more fully in "Differentiation of Activated Naïve T Cells into Effector and Memory Cells," and which play a crucial role in control of infection with intracellular bacterial, protozoal, and viral pathogens. IFN-γ activates macrophages, allowing them to control infection with intracellular pathogens, and enhances their capacity to produce IL-12 and TNF-α, which amplify IFN-γ production by NK cells and cause T cells to differentiate into IFN-γ–producing $T_H1$ cells [219,220]. IL-27 also facilitates IFN-γ production, while inducing the expression of IL-10, which dampens inflammatory and $T_H1$ responses to limit tissue injury. By contrast, IL-23 favors IL-17–producing $T_H17$ T-cell responses, in which IL-17 promotes neutrophil production, acute inflammation, and defense of extracellular pathogens.

The production of cytokines by mononuclear phagocytes normally is restricted temporally and anatomically to cells in contact with microbial products, antigen-stimulated T cells, or other agonists. When produced in excess, these cytokines are injurious [221,222]. When excess production of proinflammatory cytokines occurs systemically, septic shock and disseminated intravascular coagulation may ensue, underscoring the importance of closely regulated and anatomically restricted production of proinflammatory mediators.

Tight control of inflammation normally is achieved by a combination of positive and negative feedback regulation. TNF-α, IL-1, and microbial products that induce their production also cause macrophages to produce cytokines that attenuate inflammation and dampen immunity, including IL-10 [223] and IL-1 receptor antagonist [224]. Inflammation is also attenuated by the production of anti-inflammatory lipid mediators, including lipoxins and arrestins [225].

## CYTOKINE PRODUCTION INDUCED BY ENGAGEMENT OF TOLL-LIKE RECEPTORS AND OTHER INNATE IMMUNE PATTERN RECOGNITION RECEPTORS

Monocytes, macrophages, DCs, and other cells of the innate immune system discriminate between microbes and self [226], or things that are "dangerous" and "not dangerous," [227] through invariant innate immune pattern recognition receptors. These receptors recognize microbial structures (commonly referred to as pathogen-associated molecular patterns) or molecular danger signals produced by infected or injured host cells. Recognition is followed by signals that activate the innate immune response.

### Toll-like Receptors

TLRs are a family of structurally related proteins and are the most extensively characterized set of innate immune pattern recognition receptors. Ten different TLRs have been defined in humans [228–230]. Their distinct ligand specificities, subcellular localization, and patterns of expression by specific cell types are shown in Table 4–5 [231–234].

TLR4 forms a functional LPS receptor with MD-2, a soluble protein required for surface expression of the TLR4/MD-2 receptor complex [230,235]. This complex also recognizes the fusion protein of RSV. CD14, which is expressed abundantly on the surface of monocytes and exists in a soluble form in the plasma, facilitates recognition by the TLR4/MD-2 complex and is essential for recognition of smooth LPS present on pathogenic gram-negative bacteria [236]. TLR4-deficient and MD-2–deficient mice are hyporesponsive to LPS [237,238] and susceptible to infection with *Salmonella typhimurium* and *E. coli* [239–242]. TLR2, which forms a heterodimer with TLR1 or TLR6, recognizes bacterial lipopeptides, lipoteichoic acid, and peptidoglycan, and this recognition is facilitated by CD14. TLR2 has a central role in the recognition of gram-positive bacteria and contributes to recognition of fungi, including *Candida* species [229,243,244]. TLR5 recognizes bacterial flagellin [245]. Consistent with their role in recognition of microbial cell surface structures, these TLRs are displayed on the cell surface.

By contrast, TLR3, TLR7, TLR8, and TLR9 recognize nucleic acids: TLR3 binds double-stranded RNA, TLR7 and TLR8 bind single-stranded RNA, and TLR9

**TABLE 4–5** Human Toll-like Receptors (TLRs)

| TLR | Microbial Ligands | Site of Interaction with Ligand | Signal Transduction/Effector Molecules | Expression by Antigen-Presenting Cells |
|---|---|---|---|---|
| TLR-1 | See TLR-2 | Cell surface | MyD88-dependent induction of cytokines | Monocytes and B cells > cDCs |
| TLR-2 | Bacterial peptidoglycan, lipoteichoic acid and lipopeptides; mycobacterial lipoarabinomannan, recognition of some ligands is mediated by TLR2/TLR-1 or TLR2/TLR-6 heterodimers | Cell surface | MyD88-dependent induction of cytokines | Monocytes and cDCs > B cells |
| TLR-3 | Double-stranded RNA | Endosome | TRIF-dependent induction of type I IFNs and cytokines | cDCs |
| TLR-4 | LPS, RSV | Cell surface | MyD88-dependent and TRIF-dependent induction of cytokines; TRIF-dependent induction of type I IFNs | Monocytes > cDCs |
| TLR-5 | Flagellin | Cell surface | MyD88-induced cytokines | Monocytes > cDCs |
| TLR-6 | See TLR-2 | Cell surface | MyD88-dependent induction of cytokines | Monocytes and cDCs, B cells > pDCs |
| TLR-7 | Single-stranded RNA, imidazoquinoline drugs | Endosome | MyD88-dependent induction of type I IFNs and cytokines | pDCs and B cells >> cDCs > monocytes |
| TLR-8 | Single-stranded RNA, imidazoquinoline drugs | Endosome | MyD88-dependent induction of type I IFNs and cytokines | Monocytes and cDCs |
| TLR-9 | Unmethylated CpG DNA | Endosome | MyD88-dependent induction of cytokines and type I IFNs | pDCs and B cells |
| TLR-10 | Unknown | Unknown | Unknown | B cells > cDCs and pDCs |

*cDCs, conventional dendritic cells; IFN, interferon; LPS, lipopolysaccharide; pDCs, plasmacytoid dendritic cells; RSV, respiratory syncytial virus.*

binds nonmethylated CpG-containing DNA. These TLRs apparently function primarily in antiviral recognition and defense [231,246,247]. TLR9 also contributes to defense against bacteria and protozoans [248,249]. These TLRs preferentially recognize features of nucleic acids that are more common in microbes than mammals, but their specificity may be based on location as much as nucleic sequence: TLR3, TLR7, TLR8, and TLR9 detect nucleic acids in a location where they should not be found—acidified late endolysosomes. Individuals or mice lacking TLR3, TLR9, or a protein (UNC93B) required for proper localization of these TLRs to endosomes are unduly susceptible to infection with cytomegalovirus (CMV) and HSV [250,251].

A conserved cytoplasmic TIR (Toll/interleukin-receptor) domain links TLRs to downstream signaling pathways by interacting with adapter proteins, including MyD88 and TRIF [252–254]. MyD88 is involved in signaling downstream of all TLRs with the exception of TLR3. TLR signaling via MyD88 leads to the activation and translocation of the transcription factor nuclear factor κB (NFκB) to the nucleus and to the induction or activation by ERK/p38/JNK mitogen-activated protein kinases of other transcription factors, resulting in the production of the proinflammatory cytokines TNF, IL-1, and IL-6.

In addition to these transcription factors, activation of IRF3 or IRF7 or both is required for the induction of type I IFNs, which are key mediators of antiviral innate immunity. Activation of IRF3 and the production of type I IFNs downstream of TLR4 depend on TRIF. TRIF is also essential for the activation of IRF3 and for the production of type I IFNs and other cytokines via TLR3. Conversely, TLR7, TLR8, and TLR9 use the adapter MyD88 to activate IRF7 and to induce the production of type I IFNs and other cytokines [255–258]. Consistent with their role in detection of bacterial, but not viral, structures, TLR2 and TLR5 do not induce type I IFNs.

Similar to the production of type I IFNs, the production of IL-12 and IL-27 (but not of the structurally related cytokine IL-23) is dependent on IRF3 and IRF7. Consequently, signals via TLR3, TLR4, and TLR7/8, but not via TLR2 and TLR5, can induce the production of these two cytokines; by contrast, each of these TLRs except TLR3, which signals exclusively via TRIF, can induce the production of IL-23. IL-23 promotes the production of IL-17 and IL-22, which contribute to host defenses to extracellular bacterial and fungal pathogens, whereas IL-12 and IL-27 stimulate IFN-γ production by NK cells and facilitate defense against viruses and other intracellular pathogens. Through the concerted regulation of IL-12, IL-27, and type I IFNs, IRF3 and IRF7 link TLR recognition to host defenses against intracellular pathogens. Production of the anti-inflammatory and immunomodulatory cytokine IL-10 depends on STAT3 activation in addition to NFκB and mitogen-activated protein kinase activation [259].

## Other Innate Immune Pattern Recognition Receptors

Nucleotide binding domain–containing and leucine-rich repeat–containing receptors (NLRs) are a family of 23 proteins (in humans) [260,261]. These include NOD1, NOD2, and NALP3, which recognize components of bacterial peptidoglycan. NALP3 is also involved in

responses to components of gram-positive bacteria, including bacterial RNA and DNA [262]; products of injured host cells such as uric acid; and noninfectious foreign substances, including asbestos and the widely used adjuvant alum [263,264]. IPAF is involved in responses to *Salmonella*. NOD1 and NOD2 can activate mitogen-activated protein kinase and NFκB pathways and proinflammatory cytokines in synergy with TLRs [215]. By contrast, NALP3 and IPAF activate a macromolecular complex known as the inflammasome, leading to the activation of caspase 1, which is required for secretion of the proinflammatory cytokines IL-1β and IL-18.

C-type lectin receptors are a family of proteins, which include DC-SIGN, a receptor on DCs that is involved in their interaction with human immunodeficiency virus (HIV), and the macrophage mannose receptor, Dectin-1, and Dectin-2, which are expressed by DCs and macrophages. Dectin-1 and Dectin-2 act together with TLR2 ligands present on fungi to induce the production of cytokines, including TNF-α, IL-6, and IL-10. The yeast form induces IL-12 and IL-23, whereas the hyphal form induces only IL-23 [265]. The mechanistic basis for these differences is presumed to involve differential signaling via Dectin-1 and Dectin-2 in combination with TLR2, but this remains to be shown.

There are three members of the retinoic acid inducible gene (RIG)-I–like receptor (RLR) family—RIG-I, MDA-5, and LGP2 [247,266,267]. RLRs are present in the cytoplasm of nearly all mammalian cells, where they provide rapid, cell-intrinsic, antiviral surveillance. RIG-I is important for host resistance to a wide variety of RNA viruses, including influenza, parainfluenza, and hepatitis C virus, whereas MDA-5 is important for resistance to picornaviruses. RIG-I and MDA-5 interact with a common signaling adapter (MAVS or IPS-1), which, similar to TRIF in the TLR3/4 pathway, induces the phosphorylation of IRF3 to stimulate production of type I IFNs.

### Decoding the Nature of the Threat through Combinatorial Receptor Engagement

The differing molecular components of specific microbes result in the engagement of different combinations of innate immune recognition receptors. The innate immune system uses combinatorial receptor recognition patterns to decode the nature of the microbe and tailors the ensuing early innate response and the subsequent antigen-specific response to combat that specific type of infection. Extracellular bacteria engage TLR2, TLR4, or TLR5 on the cell surface and activate NLRs, providing a molecular signature of this type of pathogen. This leads to the production of proinflammatory cytokines and IL-23 to recruit neutrophils and support the development of a $T_H17$ type T-cell response (see "Differentiation of Activated Naïve T Cells into Effector and Memory Cells").

Fungal products engage TLR2 and Dectins, leading to a similar response [254,265,268]. Conversely, virus recognition via TLR3, TLR7, TLR8, TLR9, and RLRs stimulates the production of type I IFNs and IFN-induced chemokines (e.g., CXCL10), which induce and recruit CD8 and $T_H1$ cells. Nonviral intracellular bacterial pathogens also induce type I IFNs, which collaborate with signals from cell surface TLRs and NLRs to induce the production of IL-12 and IL-27, resulting in $T_H1$ type responses. The importance of these innate sensing mechanisms is underscored by strategies that pathogenic microbes have evolved to evade them and the mediators they induce (for examples, see Yoneyama and Fujita [267] and Haga and Bowie [269].

## CYTOKINE PRODUCTION, TOLL-LIKE RECEPTORS, AND REGULATION OF INNATE IMMUNITY AND INFLAMMATION BY NEONATAL MONOCYTES AND MACROPHAGES

Much of the older literature suggested that neonatal blood mononuclear cells (BMCs), consisting of monocytes, DCs, B lymphocytes, T lymphocytes, and NK lymphocytes, and monocytes were less efficient in general in the production of cytokines in response to LPS, other (often impure) TLR ligands, or whole bacteria. More recently, because of simplicity and a desire to minimize manipulations that might activate or alter the functions of these cells, many studies have been done with whole blood to which TLR ligands are added directly ex vivo. For the most part, findings from these studies are consistent with the studies done using BMCs cultured in medium containing serum or plasma. The studies shown for whole blood and BMCs in Table 4–6 report cytokines assayed in culture supernatants of whole blood or BMCs that have been stimulated with TLR agonists. Responses to TLR2 and TLR4 agonists are grouped for simplicity and because in many of the studies done years ago the LPS used was contaminated with TLR2 agonists. Because of the more than 10-fold greater abundance of monocytes compared with DCs in blood and BMCs, and the limited production by lymphocytes of cytokines in response to TLR agonists, monocytes are likely to be the predominant source for most of these cytokines. This is not true, however, for stimuli that act via TLRs (e.g., TLR3 and TLR9) or cytokines (e.g., type I IFNs) that monocytes do not produce or produce poorly.

The preponderance of the currently available data does not support the notion of a general inability of neonatal monocytes and DCs to produce cytokines, but rather suggests a difference in the nature of their response. There is a clear, substantial, and with rare exception consistent deficit in the production of cytokines involved in protection against intracellular pathogens, including type I IFNs, IL-12, and IFN-γ in response to TLR agonists (see Table 4–6). Similarly, type I IFN production in response to HSV [270] and parainfluenza virus is reduced [271,272]. This reduced production likely reflects impaired IL-12 and type I IFN production by neonatal DCs, however, and impaired IL-12–induced and type I IFN–induced IFN-γ production by NK cells. The production by neonatal BMCs of IL-18, a cytokine that acts in concert with IL-12 and type I IFNs to induce IFN-γ production by NK cells, is also modestly reduced (approximately 65% of adult cells) [273]. In one study, IL-12 production by adult and neonatal BMCs was similar when they were stimulated with whole gram-positive

**TABLE 4–6** Toll-like Receptor (TLR)–Induced Cytokine Production by Neonatal versus Adult Cells*

or gram-negative bacteria [274], suggesting that activation of neonatal cells with particles that contain multiple TLR and NLR ligands may be sufficient to overcome this deficit.

With the exception of TNF-α, production by neonatal cells of cytokines central to host defense against extracellular bacterial and fungal pathogens, acute inflammation, and $T_H$17-type responses seems not to be greatly decreased and in some cases is more robust. IL-1 production by cells from term neonates and adults is similar or at most marginally reduced, whereas neonatal cells generally produce more IL-6, IL-8, and IL-23. In more limited studies with cells from preterm neonates, production of IL-8 in response to LPS was also greater than production by adult cells [275], whereas production of TNF-α and IL-6 was reduced [271,276–278]. A similar deficit in TNF-α production is evident in response to stimulation with TLR2, TLR3, and TLR5 agonists [279,280], particularly when whole blood is used or BMCs or monocytes are cultured in high (≥50%) concentrations of neonatal serum. By contrast, TNF-α production in response to TLR8 agonists or whole gram-positive or gram-negative bacteria is similar [274]. Although some early studies suggested that the production of the immunoregulatory and anti-inflammatory cytokine IL-10 by neonatal cells was reduced [281,282], most studies have found greater production of IL-10 by whole blood and equal or greater production by BMCs [271,274,280,283,284].

The basis for lower production of certain cytokines by neonatal monocytes and macrophages in response to microbial products that signal through TLRs is incompletely understood. Cell surface expression of TLR2 and TLR4 by adult and neonatal monocytes is similar [161,279,284–288], and expression of CD14, which facilitates responses to LPS and TLR2 agonists, is similar or at most slightly reduced on neonatal monocytes [161,279,285,287,289–291]. To our knowledge, there are no published data on the expression of other TLR proteins by neonatal monocytes. By reverse transcriptase polymerase chain reaction analysis, neonatal and adult monocytes contain similar amounts of TLR1 through TLR9, MD-2, CD14, MyD88, TIRAP, and IRAK4 mRNA [279]; however, monocytes are known not to express TLR3 or TLR9, clouding the interpretation of some of these findings.

One group reported that neonatal monocytes have reduced amounts of MyD88 protein [287], but found no difference between adult and neonatal monocytes in LPS-induced activation of ERK1/2 and p38 kinases and phosphorylation and degradation of IκB, events that are downstream of MyD88 [287]. Decreased expression of MyD88 is insufficient to explain the diminished induction of HLA-DR and CD40 on neonatal monocytes in response to LPS [161] or of CD40 and CD80 on neonatal monocyte-derived dendritic cells (moDCs) in response to LPS and poly I:C [271] because these TLR ligands induce costimulatory molecules by TRIF-dependent and type I IFN–dependent, but MyD88-independent pathways [228,231,292,293]. Others reported diminished activation of p38 kinase in monocytes and production of TNF in response to the TLR4 ligand LPS, but not in response to TLR8 ligands [279,285,294]; these studies were done using whole blood or cells cultured in high concentrations of autologous plasma, in contrast to the study reporting no difference in p38 activation.

Levy and colleagues [37,279] concluded that differences between neonatal and adult plasma in addition to cell intrinsic differences contribute to decreased production of TNF-α and greater or equal production of IL-6 in response to LPS and TLR2 agonists by neonatal versus adult monocytes. Compared with blood from healthy adults, neonatal cord blood contains lower amounts of soluble CD14 and similar or modestly reduced amounts of soluble LPS-binding protein; concentrations of CD14 and LPS-binding protein increase to adult levels in the first week of life and increase further in response to infection, as they do in adults [295].

The reduced amounts of these two proteins may account for the earlier observation that neonatal cord blood contains lower amounts of a soluble protein, which facilitates the response of monocytes to LPS [289]. The addition of soluble CD14 to neonatal plasma did not restore TNF-α production by neonatal monocytes, however. Rather, the authors proposed that elevated concentrations of adenosine in cord blood plasma, in concert with increased intracellular concentrations of cyclic adenosine monophosphate (cAMP) induced in neonatal monocytes by adenosine, inhibit TNF and enhance IL-6 and IL-10 production by these cells [37]. Adenosine is induced by hypoxia, suggesting that the elevated adenosine concentrations may be a transient phenomenon alleviated shortly after birth. Perhaps consistent with this possibility, the robust production of IL-6, IL-8, and IL-10 in response to stimulation with LPS and IFN-γ by neonatal BMCs was found to be transient and replaced by decreased production at 1 month of age [284]. These findings have not yet been replicated and were obtained with cryopreserved cells, and the potential contribution of adenosine to these differences is unknown. The relative similarity of findings regarding cytokine production using whole blood and BMCs cultured in heterologous serum and the absence of differences in TNF-α production in response to TLR8 agonists under any conditions suggest that cell intrinsic factors are substantially responsible for the differences between adult and neonatal cells.

## SUMMARY

Monocytes and macrophages are detected in early fetal life and are present in blood and tissues by late gestation in amount similar to adults. An exception is lung alveolar macrophages, which are few in number before birth, increase rapidly after birth in term neonates, but may be delayed in preterm neonates. Recruitment of monocytes to sites of infection and inflammation is slower than in adults. Ingestion and killing of pathogens by neonatal monocytes is as competent as in adults, but neonatal macrophages may be less efficient and be activated less efficiently by IFN-γ. Although expression by neonatal and adult monocytes of TLRs and other innate immune receptors seems not to differ greatly, their responses to stimulation via these receptors differ. In response to most, but not all, microbial stimuli, neonatal BMCs produce (1) substantially lower amounts of IL-12 and type I IFNs,

which are cytokines produced primarily by DCs and important for defense against intracellular pathogens; (2) moderately less TNF-α; (3) similar or greater amounts of other proinflammatory cytokines and IL-23, which are cytokines produced primarily by monocytes and important in defense against extracellular bacterial and fungal pathogens; and (4) similar or greater amounts of the anti-inflammatory and immunoregulatory cytokine IL-10.

## DENDRITIC CELLS—THE LINK BETWEEN INNATE AND ADAPTIVE IMMUNITY

In addition to resident macrophages, all tissues contain resident DCs. DCs are also found in the blood, where they represent approximately 0.5% to 1% of BMCs in adults. DCs derive their name from the characteristic cytoplasmic protrusions or dendrites found on mature DCs. DCs do not express cell surface molecules used to identify other white blood cell lineages, but they do express class II MHC molecules (e.g., HLA-DR), and mature DCs express much greater amounts of class II MHC than any other cell type [161,296–298]. (MHC and HLA molecules are discussed in "Antigen Presentation by Classic Major Histocompatibility Complex Molecules"). DCs are lineage marker–negative ($Lin^-$), HLA-$DR^+$ mononuclear cells and can be identified and purified on this basis.

DCs are heterogeneous. The major subtypes in humans are cDCs, often referred to as myeloid DCs, which are $CD11c^+CD123^-$, and plasmacytoid DCs (pDCs), which are $CD11c^-CD123^+$. Both of these DC subsets are derived from bone marrow progenitors that give rise to other lymphoid and myeloid cell lineages [299], although the precise lineage relationships remain controversial [300]. Production and survival of cDCs is enhanced by GM-CSF, and cells similar, although not identical, to cDCs can be generated by culturing monocytes in GM-CSF plus IL-4 to produce moDCs. By contrast, pDCs express IL-3 receptors (CD123 is IL-3Rα), and IL-3 enhances their survival in vitro. Langerhans cells are a unique type of DC found only in the epidermis, where they can be differentiated from dermal cDCs by their expression of Langerin and S100 antigens and by intracellular Birbeck granules [300,301].

Langerhans cells and dermal cDCs are found in fetal skin by 16 weeks of gestation [302], and immature cDCs are found in the interstitium of solid organs by this age. Cells with the features of immature pDCs are found in fetal lymph nodes by 19 to 21 weeks of gestation [303]. DCs constitute a similar fraction (0.5% to 1%) of BMCs in neonates, children, and adults, but pDCs predominate in cord blood, constituting about 75% of the total, whereas cDCs constitute about 75% of the total in adults [161,304–307]. The absolute number of cDCs remains constant from the neonatal period into adulthood, whereas the fraction and absolute number of pDCs decline with increasing postnatal age, reaching numbers similar to adults at 5 years of age or older [306]. The biologic significance of the predominance of pDCs in the neonatal circulation is uncertain.

### PROPERTIES AND FUNCTIONS OF CONVENTIONAL DENDRITIC CELLS

cDCs play a unique and essential role in the initiation and modulation of the adaptive immune response. cDCs in the blood and uninflamed tissues are immature, in that they express low to moderate amounts of MHC class I and class II molecules on their surface. In the steady-state conditions that prevail in uninfected individuals, there is a constant low-level turnover of cDCs. New cDCs enter from the blood, and others migrate via lymphatics to secondary lymphoid tissues where they play a central role in maintaining a state of tolerance to self-antigens by presenting them to T cells in the absence of costimulatory signals required for T-cell activation [308]. In response to infection, the influx of immature cDCs and monocytes, which can give rise to immature cDCs, from the blood is induced by inflammatory chemokines produced by resident tissue macrophages and cDCs. In these tissues, immature cDCs take up microbes and microbial antigens and at the same time are induced to express on their surface the CCR7 chemokine receptor and to lose expression of receptors for chemokines present in the tissues. This change in chemokine receptor expression enhances cDC migration via lymphatics to T cell–rich areas of the draining lymph nodes, which constitutively express chemokines that bind to CCR7 (CCL19, CCL21).

Concomitant with their migration to the draining lymph nodes, DCs mature. As they do, uptake of microbes and antigens ceases, and antigenic peptides derived from previously internalized microbes and antigens are displayed on their cell surface in the groove of MHC class I and class II molecules. These peptide–MHC complexes are present on the surface of mature DCs in great abundance, as are the costimulatory molecules, CD40, CD80 (B7-1), and CD86 (B7-2), which together allow these cells to present antigens to T cells in a highly effective manner (see "Antigen Presentation") [309]. DCs not only play a crucial role in T-cell activation, but they also influence the quality of the T-cell response that ensues through the production of cytokines [231,310,311]. IL-12, IL-27, and type I IFNs instruct naïve CD4 T cells to produce IFN-γ and to differentiate into $T_H1$ cells, which help to protect against viruses and other intracellular pathogens, whereas IL-6, TGF-β, and IL-23 induce naïve T cells to become $T_H17$ cells, which help to protect against extracellular bacteria and fungi, and $T_H2$ cells develop in the absence of these cytokines and the presence of thymic stromal lymphopoietin (TSLP) produced by epithelial cells [312]. The function and localization of cDCs are highly plastic and rapidly modulated in response to infection and inflammation, which allows them to induce and instruct the nature of the T-cell response.

DC migration and maturation can be triggered by various stimuli, including pathogen-derived products that are recognized directly by innate immune receptors; by cytokines, including IL-1, TNF-α, and type I IFNs (see Tables 4–1 and 4–2); and by engagement of CD40 on the DC surface by CD40 ligand (CD154) on the surface of activated CD4 T cells (see Table 4–4). cDCs express multiple TLRs [231,232,261,266], but do not express

TLR9 (see Table 4–5) and consequently are not activated by unmethylated CpG DNA, a potent inducer of IFN-α production by pDCs. In contrast to pDCs (and monocytes), cDCs express TLR3 (see Table 4–5), however, which, along with RIG-I, allows them to produce type I IFNs and other cytokines in response to double-stranded RNAs, including poly I:C (polyinosinic:polycytidylic acid).

## FETAL CONVENTIONAL DENDRITIC CELLS

Expression of MHC class II (HLA-DR), CD40, CD80, and CD86 on neonatal and on adult blood cDCs is similar [161,271,304]. Consistent with these findings, cord blood DCs can stimulate allogeneic cord blood T cells in vitro [305,313,314]. Whether neonatal cDCs are proficient in processing and presenting foreign antigens to T cells, however, or are as effective as adult cells in doing so is unclear from these studies. When blood was stimulated with LPS or poly I:C, neonatal cDCs matured less completely, upregulating HLA-DR and CD86 to a similar degree, but CD40 and CD80 less than adult cDCs [271]. Decreased maturation of neonatal blood cDCs was also observed in response to pertussis toxin [315]. By contrast to blood cDCs, neonatal moDCs (commonly used as a more readily available, but possibly imperfect surrogate for neonatal cDCs) have decreased allostimulatory activity; have lower expression of HLA-DR, CD40, and CD80; and upregulate CD86 expression less in response to LPS or a TLR7/8 agonist than adult moDCs [219,316–319]. Impaired upregulation of CD86 was not observed when neonatal moDCs were stimulated with these two agonists in combination or with poly I:C, suggesting that these limitations in neonatal moDC function may be overcome in certain contexts [319].

The available data regarding cytokine production by neonatal cDCs, or by moDCs used as surrogate for cDCs, are consistent with the trends observed in studies comparing neonatal whole blood and BMCs: Neonatal cDCs and moDCs produce much lower amounts of type I/$T_H$1–inducing cytokines, moderately less of the proinflammatory cytokine TNF-α, and comparable or greater amounts of other proinflammatory and $T_H$17-inducing cytokines and the anti-inflammatory and immunoregulatory cytokine IL-10 (Fig. 4–3). Data regarding cytokine production by cDCs are sparse and have been obtained by flow cytometric detection of intracellular cytokines after stimulation of whole blood or BMCs with TLR agonists. In these studies, neonatal cDCs were approximately 50% as efficient as adult cDCs at producing TNF-α in response LPS. Less difference was seen in TNF-α production in response to TLR8 agonists, and IL-1α and IL-6 production were similar in response to both (see Table 4–6) [161,320].

Because poly I:C activates cells of the blood primarily via TLR3, and cDCs are the only cells in blood that express substantial amounts of TLR3, one can infer that the modestly diminished production of type I IFNs and markedly diminished production of IL-12 by poly I:C–stimulated whole blood and BMCs reflects production by cDCs [271,320]. Likewise, the production of IFN-γ by poly I:C–stimulated neonatal whole blood and BMCs likely reflects diminished IL-12 and type I IFN production by cDCs, which results in diminished production of IFN-γ by neonatal NK cells (see "Natural Killer Cells").

These inferences and other data indicating a selective reduction in type I/$T_H$1 T cell–inducing cytokine by neonatal cells are supported by data from studies done with moDCs. With the exception of one study [321], neonatal moDCs have been shown consistently to produce much less IL-12 in response to LPS, poly I:C, and TLR8 ligands or engagement of CD40 than adult moDCs [318,319,322]. This is paralleled by reduced production of type I IFNs and of the IFN-dependent chemokines CXCL9, CXCL10, and CXCL11 [323]. Neonatal cDCs [320] and moDCs [318,323] produce comparable amounts of the p40 component common to IL-12 and IL-23, but much reduced amounts of the p35 component specific for IL-12. Diminished p35 production seems to result from a defect in IRF3 binding to and remodeling of the IL-12 promoter, whereas more proximal aspects of signaling resulting in IRF3 translocation from the cytoplasm to the nucleus seem to be intact [288,323].

Because IRF3 is also required for the production of type I IFNs in response to LPS or poly I:C, this IRF3 defect is also likely to be an important factor in the diminished production of type I IFNs. The basis for this IRF3 defect is incompletely understood. Stimulation with whole gram-positive or gram-negative bacteria induces substantial and equal IL-12 production by adult and neonatal BMCs, however [274]. Although neonatal moDCs stimulated with live *Mycobacterium bovis* bacillus Calmette-Guérin (BCG) [324]

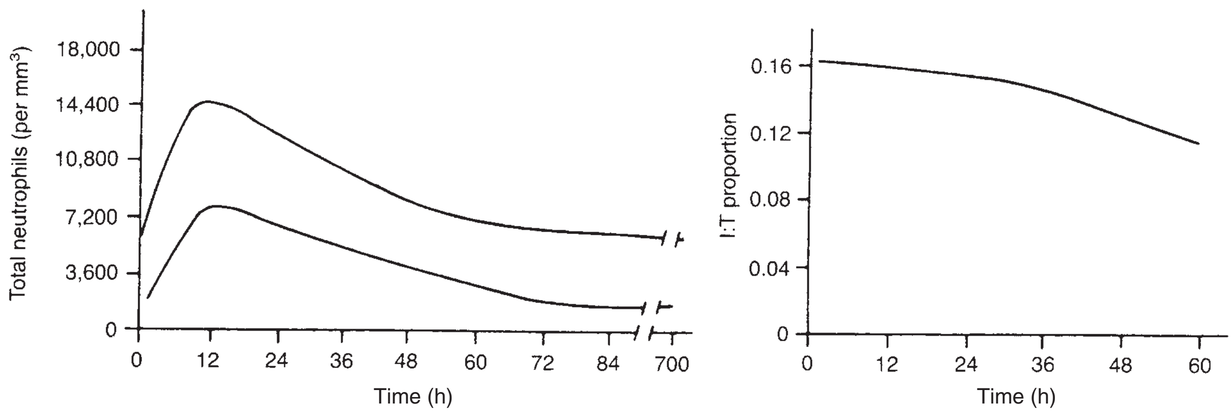

**FIGURE 4–3** Change in total number of neutrophils (*left*) and in ratio of immature to total neutrophils (I:T) (*right*) in the neonate. *(Data from Manroe BL, et al. The neonatal blood count in health and disease, I: reference values for neutrophilic cells. J Pediatr 95:89-98, 1979.)*

or with a TLR8 agonist plus LPS or poly I:C secreted much less IL-12 than adult moDCs, when moDCs were stimulated with these combinations of TLR ligands in cultures also containing autologous naïve CD4 T cells, comparable, IL-12–dependent IFN-γ production was observed [319]. Together, these observations suggest that defective production of IFN-γ–inducing cytokines, including IL-12, by neonatal DCs can be overcome by combined signaling from TLRs, NLRs, and direct physical interactions between T cells and DCs. This suggestion has not been tested directly, however.

### PROPERTIES AND FUNCTIONS OF ADULT AND NEONATAL PLASMACYTOID DENDRITIC CELLS

Immature pDCs are found in the blood, secondary lymphoid organs, and particularly inflamed lymph nodes [296,301]. The predominant function of pDCs is not antigen presentation to T cells, but rather the production of cytokines that help to protect against viral infection directly and through the induction of type I/$T_H1$ T-cell responses. Consistent with this function, pDCs do not seem to employ NLRs, C-type lectin receptors, or RLRs to recognize and respond to microbes. Rather, recognition and response are triggered through the two TLRs they express in abundance, TLR7 and TLR9 (see Table 4–5), allowing them to respond to single-stranded RNA from RNA viruses such as influenza and unmethylated CpG DNA from bacteria and viruses such as HSV [325–327].

Early studies showed diminished numbers of neonatal versus adult white blood cells producing IFN-α in response to HSV [270]. That this deficiency was attributable to diminished production by pDCs was shown more recently [304,328]. Reduced type I IFN production by neonatal pDCs was also observed in response to CMV. Neonatal pDCs also produce less type I IFNs in response to unmethylated CpG oligonucleotides and to synthetic TLR7 ligands [328]. This defect in type I IFN production seems to result in part from impaired activation and translocation of IRF7 to the nucleus [328]. Consistent with these findings, production of the NF-κB–dependent cytokine TNF-α is more modestly reduced, and production of IL-6 is comparable to adult pDCs [328].

Although pDCs in the blood and uninflamed tissues have a very limited capacity for antigen uptake and presentation, stimulation of these cells via TLR7 or TLR9 results in their upregulation of CCR7 and migration to T cell–rich areas of lymph nodes, upregulation of HLA-DR and costimulatory molecules, and increased capacity to present antigen to T cells. Neonatal blood pDCs express lower amounts of HLA-DR, CD40, CD80, CD86, and CCR7 after stimulation with TLR7 or TLR9 agonists than adults pDCs [304,328,329].

### SUMMARY

DCs are detectable by 16 weeks of gestation. At birth, the concentration of cDCs is similar and the concentration of pDCs greater than in adult blood. Although adult and neonatal blood cDCs and moDCs express on their surface the MHC class II molecule HLA-DR and costimulatory molecules in similar abundance, expression by neonatal DCs increases less in response to stimulation via TLRs. TLR-stimulated neonatal cDCs and moDCs generally produce substantially less IL-12 and type I IFNs, cytokines that contribute to early innate defenses and subsequent T cell–mediated defenses against intracellular pathogens, although they produce proinflammatory cytokines and IL-23, which are important in defense against extracellular bacterial and fungal pathogens, much more efficiently. Neonatal pDCs are also selectively deficient in the production of type I IFNs and IFN-dependent chemokines. These differences may limit the ability of neonatal DCs to activate naïve pathogen-specific T cells and in particular to induce IFN-γ–producing $T_H1$ T-cell responses, rather than $T_H17$ or $T_H2$ T-cell responses. Neonatal DCs may be able, however, to produce IL-12 and support IFN-γ production by neonatal T cells in response to combinatorial activation of innate immune receptors and in contact with T cells.

## NATURAL KILLER CELLS

### OVERVIEW AND DEVELOPMENT

NK cells are large granular lymphocytes with cytotoxic function, which, in contrast to T and B lymphocytes, are part of the innate rather than adaptive immune system. In clinical practice, NK cells are usually defined as cells that express CD56, a molecule of uncertain function, but not CD3 (i.e., $CD56^+CD3^-$) [330]. Virtually all circulating NK cells from adults also express the NK cell–specific NKp30 and NKp46 receptors [331,332]. They also express CD2 and CD161, and approximately 50% express CD57 [333,334], but these molecules are found on other cell types as well.

The fetal liver produces NK cells by 6 weeks of gestation, but the bone marrow is the major site for NK-cell production from late gestation onward. NK cells are derived from $CD34^+$ bone marrow cells that lack surface molecules specific for other cell lineages (i.e., $CD34^+Lin^-$ cells), but expressing CD7 or CD38 [335,336]. These $CD34^+CD7^+Lin^-$ cells can also differentiate into NK cells and DCs, depending on the culture conditions employed, suggesting the existence of a common T/NK/lymphoid DC progenitor [337,338]. The precise point at which there is an irreversible commitment to NK-cell lineage development is unclear. In vitro studies suggest an NK lineage cell developmental sequence in which CD161 is acquired early in NK development [339]. At the next developmental stage, NKp30, NKp46, 2B4, and NKG2D are expressed on the cell surface [340,341], followed by members of the killer cell inhibitor receptor (KIR) family, CD94-NKG2A, CD2, and CD56; the function of these molecules is discussed in the sections that follow.

NK cells are functionally defined by their natural ability to lyse virally infected or tumor target cells in a non–HLA-restricted manner that does not require prior sensitization [342]. NK cells preferentially recognize and kill cells with reduced or absent expression of self-HLA class I molecules, a property referred to as natural cytotoxicity. This is in contrast to cytotoxic CD8 T cells, which are triggered to lyse targets after the recognition of foreign antigenic peptides bound to self-HLA class I molecules or self-peptides bound to foreign HLA class I molecules. NK cells also have the ability to kill target cells that are coated with IgG antibodies, a process known as antibody-dependent

cellular cytotoxicity (ADCC). ADCC requires the recognition of IgG bound to the target cell by the NK cell FcγRIIIB receptor (CD16) [343].

Mature NK cells can be subdivided into CD56$^{hi}$CD16$^{lo}$ and CD56$^{lo}$CD16$^{hi}$ populations [344,345]. CD56$^{hi}$CD16$^{lo}$ cells usually are only a minority of mature NK cells in the circulation, but express CCR7 and L-selectin and predominate in lymph node tissue. CD56$^{hi}$CD16$^{lo}$ cells have limited cytotoxic capacity, but produce cytokines and chemokines efficiently, whereas the inverse is true for CD56$^{lo}$CD16$^{hi}$ NK cells [346]. These features suggest that the CD56$^{hi}$CD16$^{lo}$ subset could regulate lymph node T cells and DCs through cytokine secretion. Developmental studies suggest that CD56$^{hi}$CD16$^{lo}$ NK cells are less mature than CD56$^{lo}$CD16$^{hi}$ NK cells, but the precise precursor product relationship of these subsets under various conditions in vivo has not been firmly established.

NK cells are particularly important in the early containment of viral infections, especially with pathogens that may initially avoid control by adaptive immune mechanisms. Infection of host cells by the herpesvirus group, including HSV, CMV, and varicella-zoster virus (VZV), and some adenoviruses leads to decreased surface expression of HLA class I molecules, which is discussed in more detail in “Host Defense against Specific Classes of Neonatal Pathogens.” Viral protein–mediated decreases in expression of HLA class I may limit the ability of CD8 T cells to lyse virally infected cells and to clonally expand from naïve precursors. These virus-mediated effects may be particularly important during early infection, when CD8 T cells with appropriate antigen specificity are present at a low frequency. By contrast, decreased HLA class I expression facilitates recognition and lysis by NK cells. The importance of NK cells in the initial control of human herpesvirus infections is suggested by the observation that individuals with selective deficiency of NK cell numbers or function are prone to severe infection with HSV, CMV, and VZV [347].

## NATURAL KILLER CELL RECEPTORS

NK-cell cytotoxicity is regulated by a complex array of inhibitory and activating receptor-ligand interactions with target cells (Fig. 4–4). NK-cell activation is inhibited by recognition of HLA class I molecules expressed on nontransformed, uninfected cells; this recognition is presumed to provide a net inhibitory signal that predominates over activating signals. Infection of the host target cell can reduce the amount of HLA class I on the cell surface, reducing inhibitory signaling, and upregulate other molecules that promote NK-cell activation, such as MHC class I–related chains A and B (MICA and MICB).

There are two major families of NK-cell receptors that recognize HLA class I molecules in humans: KIR and CD94-containing C-type lectin families [348,349]. KIRs with a long cytoplasmic domain transmit signals that inhibit NK-cell activation; most, although not all, NK cells express one or more inhibitory KIRs on their surface. Most NK cells, including all NK cells not expressing any inhibitory KIRs, also express inhibitory CD94-NKG2A receptors [350]. KIRs bind to polymorphic HLA-B, HLA-C, or HLA-A molecules [349], whereas CD94-NKG2A binds to HLA-E, which is monomorphic (HLA molecules are discussed in “Antigen Presentation by Classic and Nonclassic Major Histocompatibility Complex Molecules”). Because HLA-E reaches the cell surface only when its peptide-binding groove is occupied by hydrophobic peptides derived from the leader

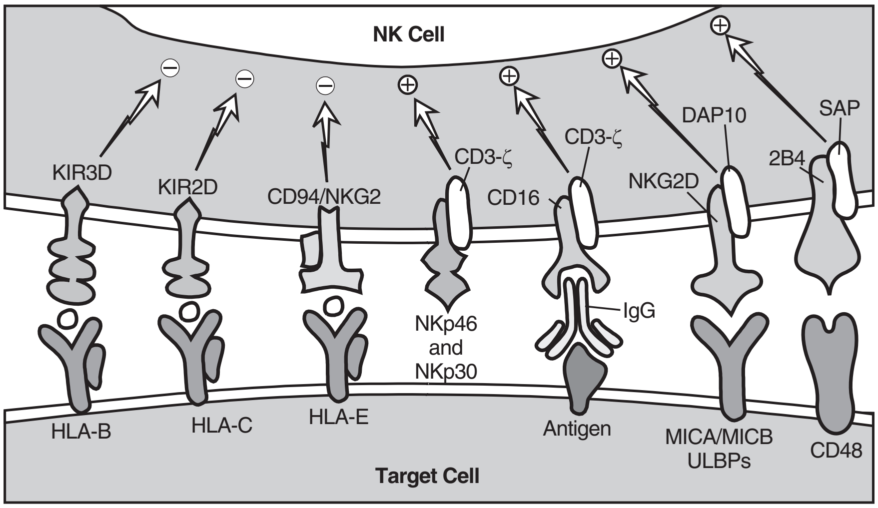

**FIGURE 4–4 Positive and negative regulation of natural killer (NK) -cell cytotoxicity by receptor/ligand interactions.** NK-cell cytotoxicity is inhibited by engagement of killer inhibitory receptors (KIR) by major histocompatibility complex (MHC) class I molecules, such as HLA-B and HLA-C. In addition, NK cells are inhibited when CD94/NKG2 complex, a member of the C-type lectin family, on the NK cell is engaged by HLA-E. HLA-E binds hydrophobic leader peptides derived from HLA-A, HLA-B, and HLA-C molecules and requires these for its surface expression. HLA-E surface expression on a potential target cell indicates the overall production of conventional MHC class I molecules. These inhibitory influences on NK-cell cytotoxicity are overcome if viral infection of the target cell results in decreased MHC class I and HLA-E levels. NK-cell cytotoxicity is positively regulated by the engagement of NKG2D, which interacts with MICA, MICB, and ULBPs; 2B4, which interacts with CD48; and natural cytotoxicity receptors, such as NKp30 and NKp46, for which the ligands on the target cell are unknown. CD16 is an Fc receptor for IgG and mediates antibody-dependent cellular cytotoxicity against cells coated with antibody (e.g., against viral proteins found on the cell surface). Positive receptors mediate their intracellular signals via associated CD3-ζ, FcER1, DAP10, or DAP12 proteins. MICA and MICB, MHC class I -related chains A and B; ULBPs, UL16-binding proteins (UL16 is a cytomegalovirus protein).

sequences of HLA-A, HLA-B, and HLA-C molecules [351], the amount of HLA-E on the cell surface reflects the overall levels of HLA-A, HLA-B, and HLA-C molecules on that cell [352].

In addition to CD94-NKG2A, a third group of inhibitory receptors that broadly recognize HLA class I molecules are the leukocyte immunoglobulin-like receptors B1 and B2 (LILRB1 and LILRB2). LILRB1 and LILRB2, also referred to as LIR1/CD85J and LIR2/CD85d, bind to HLA-A, HLA-B, and HLA-C molecules and the nonconventional class I molecules HLA-E, HLA-F, and HLA-G. HLA-G is the only HLA class I molecule constitutively expressed on the surface of fetal trophoblast. The interaction of LILRB1 and LILRB2 with HLA-G is thought to protect the placenta from injury by maternal NK cells [353].

Countering the effects of these inhibitory receptors are multiple types of activating receptors. NKG2D is found on NK cells and on certain T-cell populations. NKG2D recognizes MICA and MICB and UL16-binding proteins (ULBPs). MICA and MICB are nonclassic HLA class I molecules that are expressed on stressed or infected cells [354]. ULPBs are a group of HLA class I–like molecules expressed on many cell types that were first identified and named based on their ability to bind to the human CMV UL16 viral protein. In CMV infection, the secretion of UL16 probably limits NK cell–mediated and T cell–mediated activation by binding to ULBPs on the surface of the infected cell. Little is known of how ULBP expression is regulated during infection in vivo.

NK cells also express NKp30, NKp44, and NKp46. NKp44 and NKp46 can trigger NK cell cytotoxicity through their recognition of influenza virus hemagglutinin and Sendai (parainfluenza family) virus hemagglutinin-neuraminidase [355]. The importance of such NK cell recognition in influenza infection in vivo is unknown, however, and may be limited by the ability of NK cells to reach the respiratory epithelial cell, the major cell type that is productively infected. These receptors also recognize ligands on tumor cells and cells infected with herpesviruses, but the nature of the ligands is unknown.

The proteins 2B4 (CD244) and NTBA are members of the signaling lymphocyte activation molecule (SLAM) protein family and are expressed on most NK cells [356]. 2B4 binds to CD48, whereas the ligand for NTBA remains unclear. 2B4 and NTBA engagement triggers NK-cell activation through SLAM-associated protein (SAP), an intracellular adapter protein. X-linked lymphoproliferative syndrome is due to genetic deficiency of SAP and results in severe, often life-threatening infection from primary Epstein-Barr virus (EBV) infection, with a high associated risk for the development of lymphoma or chronic hypogammaglobulinemia [356]. SAP deficiency allows alternative molecules, the SH2-domain–containing phosphatases (SHPs), to bind the cytoplasmic tails of 2B4 and NTBA. This results in inhibition of NK-cell function, rather than merely the loss of activating function, a mechanism that may contribute to the severity and sequelae of EBV infection in these patients.

Finally, NK cells may express KIRs with short cytoplasmic tails, which, in contrast to their counterparts with long cytoplasmic tails, activate NK cells [357]. In contrast to CD94-NKG2A, CD94-NKG2C is an activating receptor complex [358]. These activating KIRs and CD94-NKG2C and their respective inhibitory forms have identical or very similar ligand specificities. How NK cells integrate the effects on natural cytotoxicity of these multiple inhibitory and activating receptors, particularly receptors that recognize the same or similar ligands, is unclear.

## NATURAL KILLER CELL CYTOTOXICITY

Target cell killing by NK cells can be divided into a binding phase and an effector phase. Numerous receptor-ligand pairs may help to mediate the initial binding, including the interaction between $\beta_2$ integrins and ICAM-1 and between CD2 and CD58 [359]. Some of these interactions may also play a role in triggering NK-cell activation, but the receptors described in the previous section seem to be the primary regulators of activation.

After binding and activation, NK cells release perforin and granzymes from preformed cytotoxic granules into a synapse formed between the NK cell and its target, leading to death by apoptosis of the target cell. NK cell–mediated cytotoxicity also may be mediated by Fas-ligand [360] or TNF-related apoptosis–inducing ligand (TRAIL) [361] expressed on the activated NK-cell surface. Fas–Fas-ligand interactions apparently are not essential for human NK-cell control of viral infections because individuals with dominant-negative mutations in Fas or Fas-ligand develop autoimmunity, but do not experience an increased severity of virus infections [362]. In contrast to natural cytotoxicity, in which perforin/granzyme–dependent mechanisms seem to be predominant, ADCC seems to use perforin/granzyme–dependent and Fas-ligand–dependent cytotoxic mechanisms [363].

## NATURAL KILLER CELL CYTOKINE RESPONSIVENESS AND DEPENDENCE

NK-cell proliferation and cytotoxicity are enhanced in vitro by cytokines produced by T cells (IL-2, IFN-$\gamma$), antigen-presenting cells (APCs) (IL-1, IL-12, IL-18, and type I IFNs), and nonhematopoietic cells (IL-15, stem cell factor, Flt3 ligand, IFN-$\beta$). IL-15, which seems crucial for the development of NK cells, also promotes the survival of mature NK cells and, similar to IL-12, increases the expression of perforin and granzymes [364,365]. NK-cell cytotoxicity in vivo is modestly decreased in mice genetically deficient in IFN-$\gamma$ [366], IL-12 [367], or IL-18 [368] and markedly depressed in mice with combined IL-12 and IL-18 deficiency. These findings suggest that IL-12 and IL-18 largely act in a nonredundant fashion to help maintain NK-cell cytotoxicity in vivo, and this maintenance is mediated, at least in part, by the induction of IFN-$\gamma$ by these cytokines. IL-23 and IL-27 are more recently described members of the IL-12 cytokine family [216]. Although their effects on NK-cell function in vivo are incompletely understood, a report suggests that a subset of NK cells found in mucosa-associated lymphoid tissue (MALT) responds to IL-23 by producing cytokines, including IL-22, that help to protect the gut from bacterial pathogens [345].

## NATURAL KILLER CELL CYTOKINE AND CHEMOKINE PRODUCTION

NK cells are also important producers of IFN-γ and TNF-α in the early phase of the immune response to viruses, and IFN-γ may promote the development of CD4 T cells into $T_H1$ effector cells (see "Differentiation of Activated Naïve T Cells into Effector and Memory Cells"). NK cell–mediated IFN-γ production may be induced by the ligation of surface $\beta_1$ integrins on the NK cell surface [369] and by the cytokines IL-1, IL-12, and IL-18 [370], which are produced by DCs and mononuclear phagocytes. The combination of IL-12 and IL-15 also potently induces NK cells to produce the CC chemokine MIP-1α (CCL-3) [371], which may help to attract other types of mononuclear cells to sites of infection, where NK cell–mediated lysis occurs [372].

NK cells from HIV-infected individuals also are able to produce various CC chemokines, including MIP-1α, MIP-1β (CCL-4), and RANTES (CCL-5), in response to treatment with IL-2 alone; these chemokines may help prevent HIV infection of T cells and mononuclear phagocytes by acting as antagonists of the HIV coreceptor CCR5 [373]. NK cells also can be triggered to produce a similar array of cytokines during ADCC in vitro, but the role of such ADCC-derived cytokines in regulating immune responses in vivo is poorly defined. Some cytokine-dependent mechanisms by which NK cells, T cells, and APCs may influence each other's function, such as in response to infection with viruses and other intracellular pathogens, are summarized in Figure 4–5.

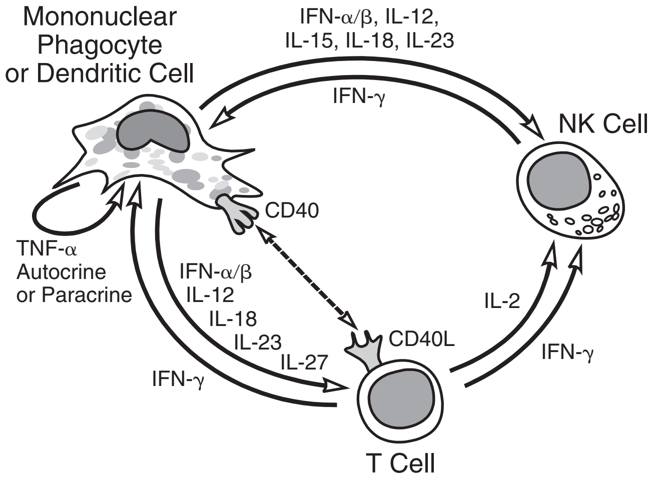

**FIGURE 4–5 Cytokines link innate and antigen-specific immune mechanisms against intracellular pathogens.** Activation of T cells by antigen-presenting cells, such as dendritic cells and mononuclear phagocytes, results in the expression of CD40 ligand and the secretion of cytokines, such as interleukin (IL)-2 and interferon (IFN)-γ. Mononuclear phagocytes are activated by IFN-γ and the engagement of CD40 with increased microbicidal activity. Mononuclear phagocytes produce tumor necrosis factor (TNF)-α, which enhances their microbicidal activity in a paracrine or autocrine manner. Mononuclear phagocytes also secrete the cytokines IFN-α/β, IL-12, IL-15, IL-18, IL-23, and IL-27. These cytokines promote $T_H1$ effector cell differentiation, and most also promote activation of natural killer (NK) cells. IL-15 (*not shown*) also is particularly important for the generation of effector and memory CD8 T cells. NK-cell activation is augmented further by IL-2 and possibly by IL-21, which are produced by CD4 T cells. Activated NK-cells secrete IFN-γ, which enhances mononuclear phagocyte activation and $T_H1$ effector cell differentiation further.

## NATURAL KILLER CELLS OF THE MATERNAL DECIDUA AND THEIR REGULATION BY HUMAN LEUKOCYTE ANTIGEN G

The maternal decidua contains a prominent population of NK cells, which may help contribute to the maintenance of pregnancy. NK cells belonging to the $CD56^{hi}CD16^{lo}$ subset, which have a high capacity for cytokine production, but low capacity for cytotoxicity, predominate. Murine studies suggest that maternal NK cell–derived cytokines, such as IFN-γ, may help to remodel the spiral arteries of the placenta. Although the NK cell populations of the decidua have a low capacity for cytotoxicity, their presence in a tissue lacking expression of HLA-A, HLA-B, and HLA-C molecules could potentially contribute to placental damage and fetal rejection. As noted previously, the expression by human fetal trophoblast of HLA-G is thought to protect this tissue from attack by maternal NK cells through binding to the inhibitory receptors LILRB1 and LILRB2 [353].

## NATURAL KILLER CELL NUMBERS AND SURFACE PHENOTYPE IN THE FETUS AND NEONATE

NK cells become increasingly abundant during the second trimester [333,374], and at term their numbers in the neonatal circulation (approximately 15% of total lymphocytes) are typically the same as or greater than in adults [333]. The fraction of $CD56^{hi}CD16^{-/lo}$ (approximately 10%) and $CD56^{lo}CD16^{+}$ NK cells (approximately 90%) is also similar [375,376]. Earlier studies of cell surface molecule expression on neonatal NK cells varied in their conclusions regarding the expression of molecules involved with adhesion, activation, inhibition, and cytotoxic mediators by neonatal NK cells. More recent studies using newer, more reliable methods suggest that neonatal NK cells have decreased expression of ICAM-1, but similar expression of other adhesion molecules; similar or greater expression of the inhibitory CD94-NKG2A complex, but reduced expression of the inhibitory LILRB1 (LIR1) receptor; similar or greater expression of the activating NKp30 and NKp46 receptors; similar or slightly reduced expression of the activating NKG2D receptor; and similar reduced surface expression of CD57 [375,376]. The abundance of the cytotoxic molecules perforin and granzyme B and FasL and TRAIL is as great or greater in neonatal NK cells as in adult NK cells [376]. These findings suggest that neonatal NK cells differ phenotypically from, and are not simply immature versions of, adult NK cells. Congenital viral or *T. gondii* infection during the second trimester can increase the number of circulating NK cells [374], which have phenotypic features of activated cells [377].

## FETAL AND NEONATAL NATURAL KILLER CELL–MEDIATED CYTOTOXICITY AND CYTOKINE PRODUCTION

The cytotoxic function of NK cells increases progressively during fetal life to reach values approximately 50% (range 15% to 60% in various studies) of the values in adult cells at term, as determined in assays using tumor cell targets and either unpurified or NK cell–enriched preparations [333,376,378,379]. Reduced cytotoxic activity by neonatal NK cells has been observed in studies using cord blood from vaginal or cesarean section deliveries or peripheral blood obtained 2 to 4 days after birth [380]. Full function is not achieved until at least 9 to 12 months of age.

Decreased cytotoxic activity by neonatal NK cells compared with adult cells also is consistently observed with HSV-infected and CMV-infected target cells [381,382]. By contrast, neonatal and adult NK cells have equivalent cytotoxic activity against HIV-1–infected cells [383]. These results suggest that ligands on the target cell or the target cell's intrinsic sensitivity to induction of apoptosis may influence fetal and neonatal NK-cell function. The mechanisms of these pathogen-related differences are unclear, but may contribute to the severity of neonatal HSV infection. Paralleling the reduction in natural cytotoxic activity of neonatal cells, ADCC of neonatal mononuclear cells is approximately 50% of that of adult mononuclear cells, including against HSV-infected targets.

The reduced cytotoxic activity of neonatal NK cells seems not to reflect decreased expression of cytotoxic molecules, but instead may result from diminished adhesion to target cells, perhaps as a result of decreased expression of ICAM-1 or diminished recycling of cells to kill multiple targets [376,379,384]. The mechanisms responsible for diminished neonatal NK-cell cytotoxicity have not been conclusively defined, however. Cytokines including IL-2, IL-12, IL-15, IFN-α, IFN-β, and IFN-γ can augment the cytotoxic activity of neonatal NK cells, as they do for adult NK cells [378,385–387], and neonatal NK cells are as cytotoxic as adult NK cells when both have been treated with IL-15 [376]. Consistent with the ability of IL-2 and IFN-γ to augment their cytolytic activity, neonatal NK cells express on their surface receptors for IL-2/IL-15 and IFN-γ in numbers that are equal to or greater than those of adult NK cells [388]. Treatment of neonatal NK cells with ionomycin and phorbol myristate acetate (PMA) also enhances natural cytotoxicity to levels present in adult NK cells [389]. This increase is blocked by inhibitors of granule exocytosis, indicating that decreased release of granules containing perforin and granzyme may contribute to reduced neonatal NK-cell cytotoxicity. Finally, decreased neonatal NK-cell cytotoxicity is not determined at the level of the precursor cells of the NK-cell lineage: Donor-derived NK cells appear early after cord blood transplantation, with good cytotoxicity effected through the perforin/granzyme and Fas–Fas-ligand cytotoxic pathways [390].

Neonatal NK cells produce IFN-γ as effectively as adult NK cells in response to exogenous IL-2, IL-12, and IL-18; HSV [391]; and polyclonal stimulation with ionomycin and PMA [375,376,391,392], but fewer neonatal NK cells express TNF-α than adult NK cells after ionomycin and PMA stimulation [392]. Neonatal NK cells produce chemokines that suppress the growth of HIV strains that use CCR5 as a coreceptor to infect CD4 T cells, but not strains that use CXCR4 as a receptor [373].

## SUMMARY

NK cells appear early during gestation and are present in normal numbers by mid-gestation to late gestation. Certain phenotypic features of NK cells differ, however, from features of adult NK cells. Neonatal NK cells seem to be as capable as adult cells of producing IFN-γ and chemokines that inhibit the ability of CCR5-trophic HIV strains to infect CD4 T cells, but may produce less TNF-α and chemokines that inhibit infection by CXCR4-trophic strains of HIV. Compared with adult NK cells, neonatal NK cells have decreased cytotoxicity to many types of target cells, including HSV-infected and CMV-infected cells, but not HIV-infected cells. Neonatal NK-cell cytotoxicity can be augmented by incubation with cytokines such as IL-15 in vitro, suggesting a potential immunotherapeutic strategy.

# T CELLS AND ANTIGEN PRESENTATION

## OVERVIEW

T cells are so named because most of these cells originate in the thymus. Along with B cells, which in mammals develop in the bone marrow, T cells compose the adaptive or antigen-specific immune system. T cells play a central role in antigen-specific immunity because they directly mediate and regulate cellular immune responses and play a crucial role in facilitating antigen-specific humoral immune responses by B cells. Most T cells recognize antigen in the form of peptides bound to MHC molecules on APCs. Antigen-specific T-cell receptors (TCRs) are heterodimeric molecules composed of either α and β chains (αβ-TCRs) (Fig. 4–6) or γ and δ chains (γδ-TCRs), with the amino-terminal portion of each of these chains variable and involved in antigen recognition. This variability is generated, in large part, as a result of TCR gene rearrangement of variable (V), diversity (D), and joining (J) segments. The TCR on the cell surface is invariably associated with the nonpolymorphic complex of CD3 proteins, which include CD3-γ, CD3-δ, CD3-ϵ, and CD3-ζ (see Fig. 4–6). The cytoplasmic domains of proteins of the CD3 complex include 10 immunoreceptor tyrosine-based activation motifs (ITAMs), which serve as docking sites for the lck and ZAP-70 (CD3-ζ–associated protein of 70 kDa) intracellular tyrosine kinases that transduce proximal activation signals to the interior of the cell after the TCR has been engaged by antigen.

Most T cells that bear αβ-TCR (or αβ T cells) also express on their surface the CD4 or CD8 coreceptors in a mutually exclusive manner and are commonly referred to as CD4 or CD8 T cells. Nearly all CD8 T cells recognize protein antigens in the form of peptide fragments that are 7 to 9 amino acids in length bound to MHC class I molecules of the classic type (HLA-A, HLA-B, and HLA-C in humans). CD4 T cells recognize antigen

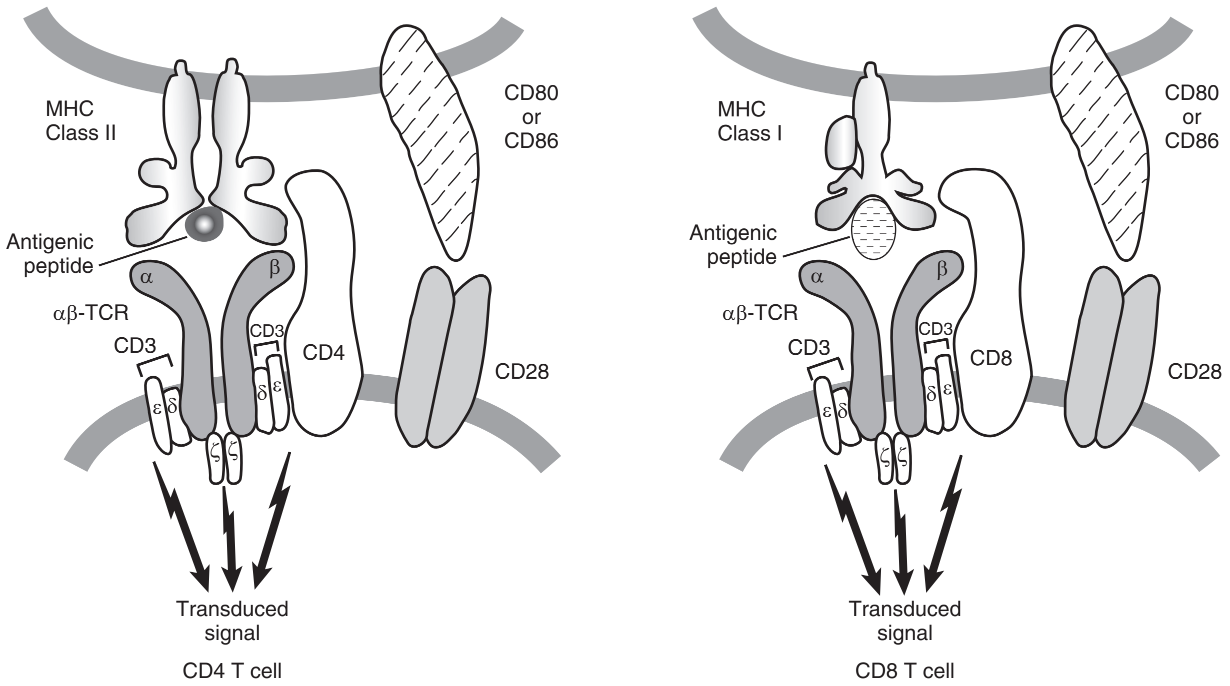

**FIGURE 4–6 T-cell recognition of antigen and activation.** αβ T-cell receptor (αβ-TCR) recognizes antigen presented by the antigen-presenting cell (APC) in the form of antigenic peptides bound to major histocompatibility complex (MHC) molecules on the APC surface. Most $CD4^+$ T cells recognize peptides bound to MHC class II, whereas most $CD8^+$ T cells recognize peptides bound to MHC class I. This MHC restriction is the result of a thymic selection process and is due in part to an intrinsic affinity of the CD4 and CD8 molecules for the MHC class II and class I molecules. When antigen is recognized, the CD3 protein complex, which is invariably associated with αβ-TCR, acts as docking site for tyrosine kinases that transmit activating intracellular signals. Interaction of the T-cell CD28 molecule with either CD80 (B7-1) or CD86 (B7-2) provides an important costimulatory signal to the T cell leading to complete activation, rather than partial activation or functional inactivation (anergy).

presented by MHC class II molecules (HLA-DR, HLA-DP, and HLA-DQ in humans); most of these antigens are in the form of peptide fragments typically 12 to 22 amino acids in length. MHC class II presentation of certain zwitterionic bacterial polysaccharides, such as those derived from *Bacteroides fragilis*, can also occur [17].

APCs, which include DCs, mononuclear phagocytes, and B cells, constitutively express MHC class I and class II molecules, which allows them to present antigenic peptides to CD8 and CD4 T cells. DCs are particularly important for presentation to T cells that are antigenically naïve and that have not been previously activated by foreign antigen. γδ T cells, which mainly recognize stress-induced molecules rather than peptide–MHC complexes, have distinct immune functions from αβ T cells and are discussed later in a separate section.

# ANTIGEN PRESENTATION BY CLASSIC MAJOR HISTOCOMPATIBILITY COMPLEX MOLECULES

## Major Histocompatibility Complex Class Ia

MHC class Ia proteins are heterodimers of a heavy chain that is polymorphic and a monomorphic light chain, $\beta_2$-microglobulin. Antigenic peptides 8 to 10 amino acids in length bind to a cleft formed by two domains of the heavy chain (Fig. 4–7; see also Fig. 4–6). There are three different types of MHC class Ia molecules—HLA-A, HLA-B, and HLA-C; all three types are highly polymorphic, and 548, 936, and 300 different molecularly defined alleles have been described for HLA-A, HLA-B, and HLA-C [393]. The greatest degree of polymorphism is found in the region encoding the antigenic cleft, which results in there being considerable differences among individuals in their ability to present antigenic peptides to T cells. The CD8 molecule has an affinity for a non-variable domain of the heavy chain that is not involved in binding peptide and that contributes to T-cell activation.

Most peptides bound to MHC class Ia molecules are derived from proteins synthesized de novo within host cells (see Fig. 4–7), with the bulk derived from recently translated proteins, rather than as a result of turnover of stable proteins. This helps minimize any delay in detecting pathogen-derived peptides that may result from recent infection [394]. In uninfected cells, these peptides are derived from host proteins; that is, they are self-peptides. Recently synthesized host proteins that are targeted for degradation (e.g., because of misfolding or defective post-translational modification) are a major source of self-peptides that bind to MHC class Ia. After intracellular infection, such as with a virus, peptides derived from viral proteins endogenously synthesized within the cell bind to and are presented by MHC class Ia. Antigenic peptides are derived predominantly by enzymatic cleavage of proteins in the cytoplasm by the proteasome. A specific peptide transporter or pump, the

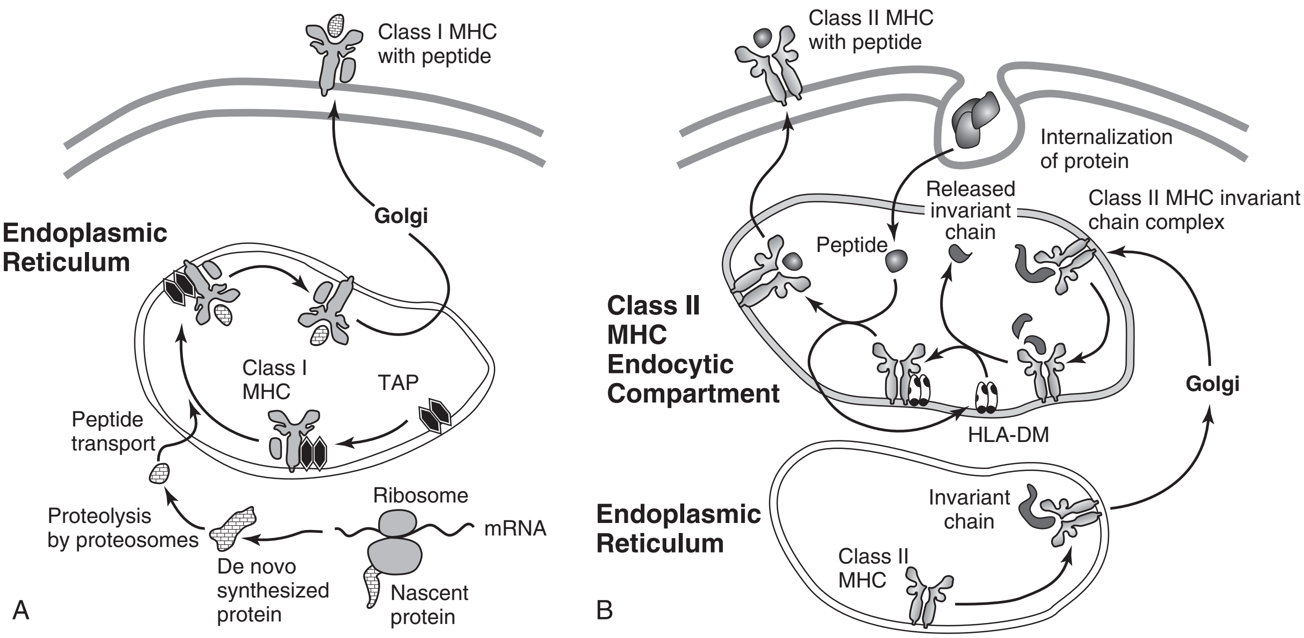

**FIGURE 4–7 Intracellular pathways of antigen presentation. A,** Foreign peptides that bind to major histocompatibility complex (MHC) class I are predominantly derived from cytoplasmic proteins synthesized de novo within the cell. Viral proteins entering cells after fusion of an enveloped virus with the cell membrane may also enter this pathway. Dendritic cells are particularly efficient at taking up proteins for the MHC class I pathway by micropinocytosis or macropinocytosis. These cells can also transfer proteins taken up as part of necrotic or apoptotic debris into the MHC class I pathway, a process known as cross-presentation. Cytoplasmic proteins are degraded by proteasomes into peptides, which enter into the endoplasmic reticulum via the transporter associated with antigen processing (TAP) system. Peptide binding by de novo synthesized MHC class I occurs within the endoplasmic reticulum. **B,** Foreign peptides that bind to MHC class II are mainly derived from internalization proteins found in the extracellular space or that are components of cell membrane. The invariant chain binds to recently synthesized MHC class II and prevents peptide binding until a specialized cellular compartment for MHC class II peptide loading is reached. In this compartment, the invariant chain is proteolytically cleaved and released, and peptides derived from internalized proteins may now bind to MHC class II. The HLA-DM molecule facilitates the loading of peptide within this compartment. In dendritic cells, proteins that enter into the MHC class II antigen presentation pathway can be transferred to the MHC class I pathway by cross-presentation.

transporter associated with antigen processing (TAP), shuttles peptides formed in the cytoplasm to the endoplasmic reticulum, where peptides are able to bind to recently synthesized MHC class Ia molecules. Peptide binding stabilizes the association of the heavy chain with $\beta_2$-microglobulin in this compartment and allows the complex to transit to the cell surface.

MHC class Ia molecules and the cell components required for peptide generation, transport, and MHC class Ia binding are virtually ubiquitous in the cells of vertebrates. The advantage to the host is that cytotoxic CD8 T cells can recognize and lyse cells infected with intracellular pathogens in most tissues. The abundance of MHC class I molecules is increased by exposure to type I IFNs and IFN-γ, which also can induce the expression of modest amounts of MHC class Ia molecules on cell types that normally lack expression, including neuronal cells.

DCs are unique in their ability to present antigenic peptides on MHC class Ia molecules by an additional pathway, known as cross-presentation, in which extracellular proteins that are taken up as large particles (phagocytosis), as small particles (macropinocytosis), or in soluble form (micropinocytosis) are transferred from endocytic vesicles to the cytoplasm. When these proteins are in the cytoplasm, they undergo proteasome-mediated degradation and loading onto MHC class Ia molecules through TAP. Cross-presentation is essential for the induction of primary CD8 T-cell responses directed toward antigens of pathogens that do not directly infect APCs (e.g., most viruses) and cannot be directly loaded into the MHC class Ia pathway. Cross-presentation is enhanced by exposure of DCs to type I IFNs [395]. UNC-93B1, a protein that is important for TLR signaling and antiviral host defense (see section on TLRs earlier and antiviral host defenses later), has also been implicated as playing a role in cross-presentation by murine APCs [396], but it is unclear if this applies to human APC cross-presentation. Cross-presentation may also be facilitated by the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex [397], which helps limit acidification that can destroy protein-derived epitopes.

## Major Histocompatibility Complex Class II

In MHC class II molecules, an α and a β chain contribute to the formation of the antigenic peptide-binding groove (see Fig. 4–7). The three major types of human MHC class II molecules—HLA-DR, HLA-DP, and HLA-DQ—are highly polymorphic, particularly in the region encoding the peptide-binding cleft. In humans and primates, HLA-DR allelic diversity is mediated solely by the HLA-DR β chain because the HLA-DR α chain is monomorphic. HLA-DRβ protein is encoded mainly at the DRB1 locus, for which there are 556 known alleles

that encode distinct amino acid sequences [393]. Some HLA-DRβ proteins may be encoded by less polymorphic loci, such DRB3, that are closely linked to DRB1. HLA-DPα, HLA-DPβ, HLA-DQα, and HLA-DQβ gene loci are highly polymorphic, consisting of 16 (HLA-DPα), 115 (HLA-DPβ), 25 (HLA-DQα), and 69 (HLA-DQβ) known alleles that encode distinct proteins [393]. HLA-DR is expressed at substantially higher levels than HLA-DP or HLA-DQ, which probably accounts for its predominance as the restricting MHC class II type for many CD4 T-cell immune responses.

Analogous to the CD8 molecule and MHC class I, the CD4 molecule has affinity for a domain of the MHC class II β chain distinct from the region that forms part of the peptide-binding groove. In contrast to MHC class Ia, peptides that bind to MHC class II proteins are derived mostly from phagocytosis or endocytosis of soluble or membrane-bound proteins or from pathogens that are sequestered in intracellular compartments (see Fig. 4–7). Autophagy, which removes damaged organelles from the cytoplasm and provides nutrients to the cell during starvation, also may be an important source of peptides.

In the absence of foreign proteins, most peptides bound to MHC class II molecules are self-peptides derived from proteins found on the cell surface or secreted by the cell. Newly synthesized MHC class II molecules associate in the endoplasmic reticulum with a protein called the invariant chain, which impedes their binding of endogenous peptides in this compartment. The loading of exogenously derived peptides and the removal of invariant chain from MHC class II are facilitated by HLA-DM (see Fig. 4–7), a nonpolymorphic heterodimeric protein, and likely occur in a late phagolysosomal compartment. Most MHC class II peptides are 14 to 18 amino acids in length, although they can be substantially longer.

The distribution of MHC class II in uninflamed tissues is much more restricted than MHC class Ia, with constitutive MHC class II mainly limited to APCs, such as DCs, mononuclear phagocytes, and B cells. Limiting MHC class II expression in most situations to these cell types makes teleologic sense because the major function of these professional APCs is to process foreign antigen for recognition by CD4 T cells. Many other cell types can be induced to express MHC class II and, in some cases, present antigen to CD4 T cells, as a consequence of tissue inflammation or exposure to cytokines, particularly IFN-γ, but also TNF-α or GM-CSF (see Tables 4–1 and 4–2).

### Major Histocompatibility Complex Molecule Expression and Antigen Presentation in the Fetus and Neonate

The expression of MHC class I and class II molecules by fetal tissues is evident by 12 weeks of gestation, and all of the major APCs, including mononuclear phagocytes, B cells, and DCs [398], are present by this time. Fetal tissues are vigorously rejected after transplantation into non–MHC-matched hosts, indicating that surface MHC expression is sufficient to initiate an allogeneic response, probably by host cytotoxic CD8 T cells. This vigorous allogeneic response does not exclude more subtle deficiencies in antigen presentation in the fetus and neonate, however, particularly under more physiologic conditions that more stringently test APC function. The amount of MHC class Ia expression on neonatal lymphocytes is lower than on adult cells [399], and this could limit the ability of lymphocytes infected by pathogens to be lysed by cytotoxic CD8 T cells.

For technical reasons, most studies of human neonatal dendritic antigen presentation have involved using autologous or allogeneic moDCs to activate T cells. Neonatal and adult moDCs are similarly efficient in processing exogenous protein and present antigenic peptides to autologous naïve T cells with similar efficiency to become nonpolarized effector cells capable of producing $T_H1$ (IFN-γ) and $T_H2$ (IL-13) cytokines. A similar ability to cross-present soluble protein to CD8 T cells has also been reported [329], although neonatal moDC function may not be indicative of function of human primary neonatal cDCs.

One study found that neonatal monocytes were inferior to adult monocytes in presentation of either whole protein antigen, in which antigen processing was required, or exogenous peptide to HLA-DR–expressing T-cell hybridomas [400]. This inferiority was not accounted for by decreased expression of either MHC class II or costimulatory molecules, such as CD80 or CD86, by neonatal monocytes, and because this applied to whole protein and exogenously added peptides, a defect only in antigen processing is unlikely. The precise mechanisms are unclear, but could involve neonatal monocyte limitations in adhesion to or immunologic synapse formation with T cells [400] (discussed in "Memory T-Cell Activation"). A substantial fraction of MHC class II molecules on neonatal, but not adult, B cells are "empty"—that is, they lack peptides in the binding groove [401]. Neonatal B cells may be functionally limited as APCs.

## NONCLASSIC ANTIGEN PRESENTATION MOLECULES

### HLA-E

HLA-E is a nonclassic and essentially monomorphic class Ib MHC molecule similar to conventional MHC class Ia in its dependency on the proteasome for the generation of peptides and its obligate association with $\beta_2$-microglobulin. In contrast to conventional MHC class Ia molecules, HLA-E preferentially binds hydrophobic peptides, including peptides derived from the amino-terminal leader sequences of most alleles of HLA-A, HLA-B, and HLA-C [402]. Low levels of HLA-E surface expression can be detected on most cell types, consistent with the nearly ubiquitous distribution of HLA-A, HLA-B, and HLA-C and the TAP system. An important role for HLA-E is to interact with the CD94-containing receptors on NK lymphocytes and to regulate their function (see earlier section on NK-cell inhibitory receptors). HLA-E is also expressed by fetal-derived extravillous trophoblasts of the human placenta. Because trophoblast cells lack expression of most conventional MHC class Ia molecules, the surface expression of HLA-E may limit the lysis of these cells by maternal or fetal NK cells [403].

## HLA-G

HLA-G, which, similar to HLA-E, is expressed at high levels by human cytotrophoblasts within the maternal uterine wall, has limited polymorphism, but otherwise is quite similar to MHC class Ia in its association with $\beta_2$-microglobulin and structure. HLA-G occurs as either an integral membrane protein or a secreted isoform [404]. Similar to HLA-E, HLA-G is capable of engaging regulatory receptors on NK cells and may serve to limit NK cell–mediated cytotoxicity against trophoblasts (see "Natural Killer Cells of the Maternal Decidua and Their Regulation by Human Leukocyte Antigen G"). In this context, the hydrophobic leader sequence of HLA-G may provide a peptide that is particularly effective for HLA-E–mediated regulation of NK cell cytotoxicity [403]. Soluble HLA-G is present at relatively high levels in the serum of pregnant women [404] and in lower amounts in cord blood and in the peripheral blood of nonparous women and men. The in vivo function of soluble HLA-G is unclear, but it may inhibit immune responses. Consistent with this proposed function, soluble HLA-G (and class Ia molecules) can induce Fas (CD95)-dependent apoptosis of activated CD8 T cells, by engaging CD8 and increasing surface expression of Fas-ligand (CD95L) [405,406].

## Major Histocompatibility Complex Class I–Related Chains A and B

MICA and MICB have limited but clear homology with conventional MHC class I molecules. In contrast to conventional MHC class I, they lack a binding site for CD8, are not associated with $\beta_2$-microglobulin, and do not seem to be involved with the presentation of peptide antigens. Instead, these molecules are expressed on stressed intestinal epithelial cells, such as cells experiencing heat shock, and on other cell types in response to infection with viruses, such as cells of the herpesvirus group. The expression of MICA and MICB transcripts in the unstressed cell is under negative control by cellular microRNAs, which themselves are downregulated by stress [407]. MICA and MICB are ligands for NKG2D found on most NK cells, some CD8 T cells, and certain populations of γδ T cells (e.g., cells expressing Vγ9Vδ2 TCRs) [408]. NKG2D can either directly activate or act in concert with TCR-mediated signals to activate the cells that express it [409].

## CD1

The human CD1 locus includes five nonpolymorphic genes—CD1a through CD1e. CD1 molecules associate with $\beta_2$-microglobulin, but have limited structural homology with either MHC class I or MHC class II proteins. In humans, they are expressed mainly on APCs, including DCs. CD1a, CD1b, and CD1c are involved in the presentation of diverse types of lipids unique to microorganisms, such as mycolic acids, glucose monomycolate, sulfolipid, phosphatidyl mannosides, and mannosylated lipoarabinomannan or mycobacteria, to clonally diverse T cells [410]. CD1d, in contrast, presents lipid antigens to natural killer T (NKT) cells, a specialized T-cell population with a highly restricted αβ-TCR repertoire (discussed in more detail subsequently) [411]. The microbial lipids presented by CD1d include diverse microbial sources, such as *Borrelia burgdorferi*, *Sphingomonas* species, and *Leishmania donovani*. CD1e, which is expressed only intracellularly, facilitates antigen processing of the mycobacterial lipid hexamannosylated phosphatidyl-*myo*-inositol, so that it can be displayed on the APC cell surface in association with CD1b [410].

Antigen processing and loading of CD1 molecules involves endocytic pathways, at least some of which intersect with pathways involved in peptide loading of MHC class II molecules [410]. The CD1 molecules also are capable of presenting self-lipids, such as phosphatidylinositol and $G_{M1}$ ganglioside. This recognition of self-lipids, which typically involves lower affinity interactions with CD1 than that of microbial-derived ligands, may be involved in the positive selection of CD1-restricted T cells in the thymus, analogous to the process by which peptide–MHC complexes with relatively low affinity for the TCR play such a role (see later section on thymocyte development). Little is known of the adequacy of antigen presentation by CD1 molecules in the human fetus or neonate.

# PROTHYMOCYTES AND EARLY THYMOCYTE DIFFERENTIATION

## Thymic Ontogeny

With the exception of a subset of the T cells found in the gut and perhaps the liver, most αβ T cells develop from immature progenitor cells within the unique microenvironment of the thymus. The thymus does not have a population of self-replenishing stem cells and requires a continual input of thymocyte progenitor cells (prothymocytes) to maintain thymocytopoiesis. The entry of prothymocytes from the circulation into the thymus seems to occur cyclically rather than continuously, resulting in waves of thymocyte development.

The thymic rudiment (lacking hematopoietic cells) arises from the endoderm of the third pharyngeal pouch [412] at weeks 4 to 5 of gestation. An interstitial deletion of a 1.5- to 3-Mb region of the human chromosome 22q11.2 region is the most frequent genetic cause of DiGeorge syndrome and velocardiofacial syndrome and results in hypoplasia of tissues deriving from the third pharyngeal pouches, including the thymus [413]. A murine model suggests that haploinsufficiency for two genes located within the human 22q11.2 deleted segment—Tbx1 and Crkl—are responsible for this hypoplasia [414].

The prothymocyte is an early derivative of, but not identical to, a fully totipotent HSC. The human prothymocyte of the fetal bone marrow has a $CD7^{+}CD34^{hi}CD45RA^{hi}Lin^{-}$ (lacking markers for the mature T-cell, B-cell, NK-cell, erythroid cell, and myeloid cell lineages) surface phenotype [415]. This cell population is replaced in the postnatal bone marrow by a $CD7^{-}CD10^{+}CD24^{-}CD34Lin^{-}$ cell population as the likely major prothymocyte population [416]. Human fetal prothymocytes not only have T-cell differentiation potential, but also retain the capacity to differentiate along B-cell, NK-cell, and myeloid cell, but not erythroid

cell lineages [415]. Whether postnatal human prothymocytes retain a capacity for myeloid and erythroid lineage differentiation is controversial [416,417].

The first waves of human fetal CD7$^{+}$ prothymocytes probably enter into the thymic rudiment when it lacks a vasculature at about 8 weeks of gestation [415], with later ones entering through postcapillary venules at the cortical medullary junction. These prothymocytes derive from the bone marrow, and the human fetal liver does not seem to play a role in producing prothymocytes [415]. Newly entering prothymocytes rapidly encounter perivascular thymic epithelial cells [415] that express the Delta-like ligands. These ligands engage Notch 1 on the prothymocyte cell to promote its T-cell lineage commitment rapidly, as evidenced by the expression of T cell–specific genes and the suppression of B-cell development. The rapid induction of the expression of these T cell–specific genes may be facilitated by their having an open chromatin structure starting at the HSC stage [418]; this chromatin configuration likely continues through the prothymocyte stage.

Intrathymic cellular progeny of the entering prothymocyte gives rise to the three major subsets of thymocytes characteristic of the second-trimester and third-trimester fetal and postnatal human thymus (Fig. 4–8). These subsets are named according to their pattern of surface expression of CD4 and CD8 and are characterized further by their surface expression of αβ-TCR complexes. Thymocytes can be classified as double-negative (CD4$^{-}$CD8$^{-}$), which express little or no CD4 or CD8 (hence, double-negative) or αβ-TCR–CD3 (and sometimes referred to as triple-negative) and are direct products of the entering prothymocyte; double-positive (CD4$^{hi}$CD8$^{hi}$), which express medium levels of αβ-TCR–CD3 and are derived from the most mature double-negative cells; and single-positive (CD4$^{hi}$CD8$^{-}$ and CD4$^{-}$CD8$^{hi}$), which express high levels of αβ-TCR–CD3 and are derived from double-positive cells. In humans, there is also an intermediate stage between double-negative and double-positive thymocytes that is characterized by a CD4$^{lo}$CD8$^{-}$CD3$^{-}$ (immature single-positive) surface phenotype [419].

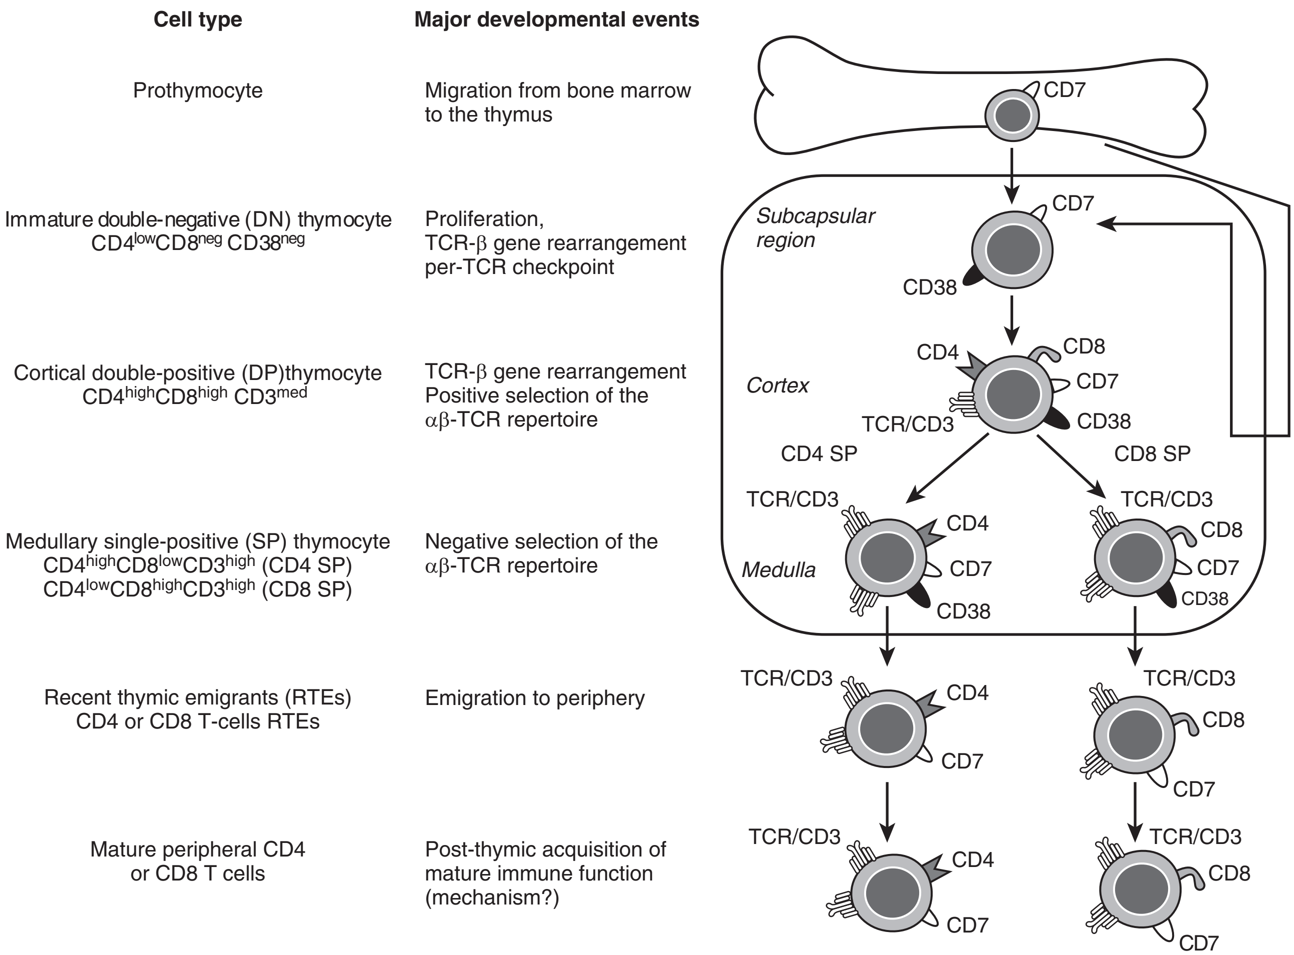

**FIGURE 4–8 Putative stages of human αβ T-cell receptor–positive (TCR$^{+}$) thymocyte development.** Prothymocytes from the bone marrow or fetal liver, which express CD7, enter the thymus via vessels at the junction between the thymic cortex and medulla. They differentiate to progressively more mature αβ-TCR$^{+}$ thymocytes, defined by their pattern of expression of αβ-TCR/CD3 complex, CD4, CD8, and CD38. TCR-α and TCR-β chain genes are rearranged in the outer cortex. Positive selection occurs mainly in the central thymic cortex by interaction with thymic epithelial cells, and negative selection occurs mainly in the medulla by interaction with thymic dendritic cells. Following these selection processes, medullary thymocytes emigrate into the circulation and colonize the peripheral lymphoid organs as CD4$^{+}$ and CD8$^{+}$ T cells with high levels of αβ-TCR/CD3 complex. These recent thymic emigrants (RTEs) also contain signal joint T-cell receptor excision circles (sjTRECs), which are a circular product of TCR gene rearrangement. Most RTEs probably lack CD38 surface expression. In contrast, in neonates, most peripheral T cells retain surface expression of CD38 and have high amounts of sjTRECs compared with adult peripheral T cells.

A fetal triple-negative ($CD3^-CD4^-CD8^-$) thymocyte population that is also $CD1a^-CD7^+CD34^{hi}CD45RA^{hi}$ likely includes prothymocytes that have recently immigrated into the thymus [415]. In the postnatal thymus, this most recent thymic immigrant population is replaced by a triple-negative population that is $CD1a^-CD7^-CD10^+$ $CD34^{hi}CD45RA^{hi}$. Triple-negative thymocytes undergo progressive differentiation that involves alterations in expression of CD34, CD38, and CD1a in which the progeny of recent thymic immigrants progressively differentiate into $CD1a^+CD34^-CD38^-$, $CD1a^+CD34^-CD38^+$, and $CD1a^+CD34^+CD38^+$ thymocytes to become $CD4^{lo}CD8^-$ $CD3^-$ (immature single-positive) cells [417]. During this differentiation, thymocytes move outward in the cortex toward the subcapsular region, a process that is accompanied by proliferation driven by the binding of Wnt, IL-7, and Flt3-ligand to their specific receptors on the thymocyte cell surface [420]. When thymocytes reach the outer cortex, they reverse course and move from the outer to the inner cortex as double-positive thymocytes [421]. Finally, double-positive cells become single-positive thymocytes in the medulla, which exit the thymus as mature but naïve (i.e., they have not yet encountered and are naïve to the antigen they are capable of recognizing) T cells probably through blood vessels located in the medulla (see Fig. 4–8).

Thymocytes expressing proteins that are characteristic of T-lineage cells, including CD4, CD8, and αβ-TCR–CD3 complex, are found shortly after the initial colonization at 8.5 weeks of gestation [422]. By 12 weeks of gestation, the pattern of expression of numerous other proteins expressed by thymocytes, such as CD2, CD5, CD38, and the CD45 isoforms, matches the pattern in the postnatal thymus. Concurrently, a clear architectural separation between the thymic cortex and medulla is evident [423], with Hassall corpuscles observable in the thymic medulla shortly thereafter [424]. By 14 weeks of gestation, the three major human thymocyte subsets (double-negative [$CD4^-CD8^-$], double-positive [$CD4^+CD8^+$], and mature single-positive [$CD4^+CD8^-$ and $CD4^-CD8^+$]) characteristic of the postnatal thymus are found (see Fig. 4–8). Fetal thymocyte expression of the chemokine receptors CXCR4 and CCR5, which also are major coreceptors for entry of HIV-1, has been found by 18 to 23 weeks of gestation [425] and is likely to be present earlier.

Thymic cellularity increases dramatically during the second and third trimesters. Transient thymic involution, mainly the loss of cortical double-positive ($CD4^{hi}CD8^{hi}$) thymocytes, which is evident within 1 day after birth, probably begins at the end of the third trimester [426]. This involution may be a consequence of the elevation in circulating levels of glucocorticoids that occurs during the third trimester before delivery. Thymic recovery is evident by 1 month after delivery and is paralleled by a sharp decline in glucocorticoid levels within hours after birth [426]. This transient involution is followed by a resumption of increased thymic cellularity, with peak cellularity and thymus size probably attained at about 1 year of age [427]. When complete thymectomy is performed during the first year of life, subsequent circulating numbers of CD4 and CD8 T cells are decreased, indicating the importance of postnatal thymocyte production for the maintenance of the peripheral T-cell compartment [428].

There is gradual replacement of thymic cellularity of the cortex and medulla by fat after early childhood, with single-positive thymocytes within the medulla being relatively spared compared with cortical double-positive thymocytes [429]. Nevertheless, the thymus remains active in T-cell production through the fourth decade of life [430–433] and is capable of increasing its output of antigenically naïve T cells in response to severe T-cell lymphopenia (e.g., after intense cytoablative chemotherapy or treatment with highly active combination antiretroviral therapy for HIV infection) [434]. The mechanisms by which increased thymocytopoiesis is triggered by severe lymphopenia are unclear, but may include increased production of IL-7, which is plausible as IL-7 administration increases output of recent thymic emigrants (RTEs) in healthy adults [435].

# INTRATHYMIC GENERATION OF T-CELL RECEPTOR DIVERSITY

## Overview

T (and B) lymphocytes undergo a unique developmental event—the generation of a highly diverse repertoire of antigen receptors through DNA recombination, a process referred to as V(D)J recombination. This diversity is generated through the random rearrangement and juxtaposition into a single exon of variable (V), diversity (D), and joining (J) segments to form in each cell a unique TCR α and TCR β gene sequence (Fig. 4–9). The process of V(D)J recombination is restricted to immature T-lineage and B-lineage cells, the only cell types that express the two recombination-activating genes, *RAG1* and *RAG2*. Recombination of the TCR genes is restricted further to cells of the T-lymphocyte rather than B-lymphocyte lineage by mechanisms (e.g., histone acetylation) that allow RAG access to the TCR genes only in T-cell progenitors. The RAG proteins are critically involved in the initiation of the recombination process—they recognize and cleave conserved sequences flanking each V, D, and J segment.

Other proteins, including a high-molecular-weight, DNA-dependent protein kinase and its associated Ku70 and Ku80 proteins, DNA ligase IV and its associated XRCC4 protein, Artemis, and Cernunnos-XLF, perform nonhomologous DNA end-joining (NHEJ) repair of the cleaved V(D)J segments [436]. In contrast to RAG proteins, these other proteins involved in NHEJ DNA repair are expressed in most cells and are involved in repair of double-stranded DNA breaks induced by cell damage, such as radiation. Genetic deficiency of any of the proteins involved in the rearrangement process results in a form of severe combined immunodeficiency (SCID) because T-cell and B-cell development depends on the surface expression of rearranged TCR (T cell) and immunoglobulin (B cell) genes [437].

The complementarity-determining regions (CDRs) of the TCR and immunoglobulin molecules are those that are involved in forming the three-dimensional structure that binds with antigen. The V segments encode the CDR1 and CDR2 regions for both TCR chains. The CDR3 region, where the distal portion of the V segment joins the (D)J segment, is a particularly important

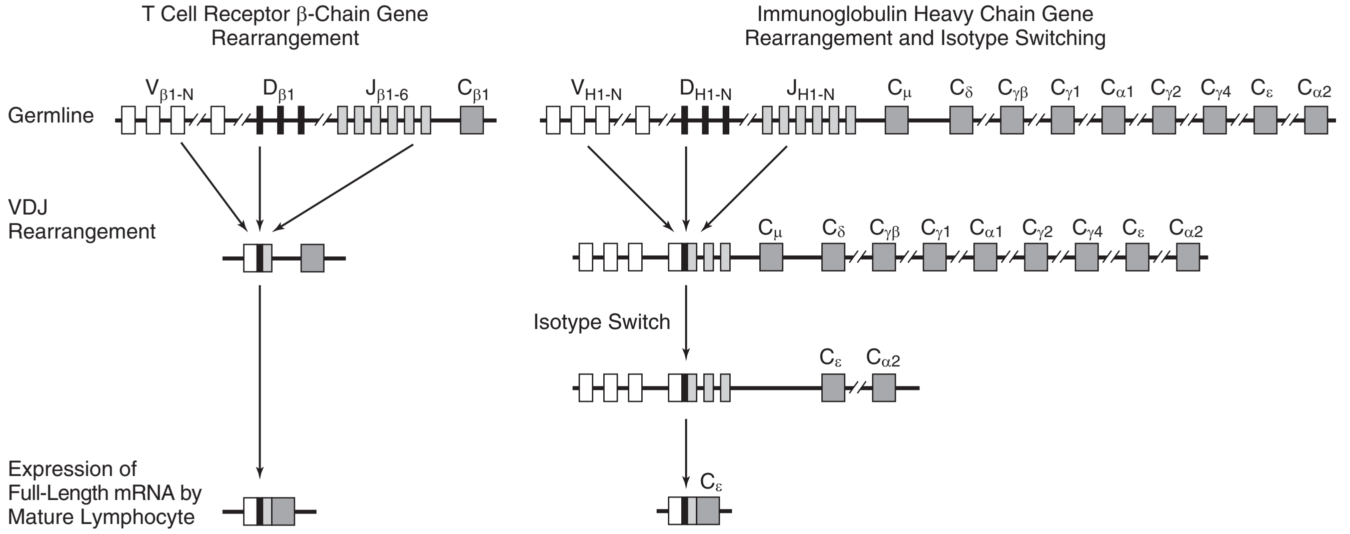

**FIGURE 4–9 T-cell receptor (TCR) and immunoglobulin genes are formed by rearrangement in immature lymphocytes.** TCR-β chain gene and the immunoglobulin heavy chain genes are shown as examples. A similar process is involved with rearrangement of the TCR-α, TCR-γ, and TCR-δ chain genes and with immunoglobulin light chain genes. Rearrangement involves the joining of dispersed segments of V (variable), D (diversity), and J (joining) gene segments with the deletion of intervening DNA. This process allows expression of a full-length mRNA transcript that can be translated into a functional protein, provided that there are no premature translational stop codons. Immunoglobulin heavy chain genes undergo an additional rearrangement called isotype switching, in which the C (constant) region segment is changed without alteration of the antigen combining site formed by the V, D, and J segments. The isotype switch from IgM to IgE is shown.

source of αβ-TCR diversity for peptide-MHC recognition and is the center of the antigen-binding site for peptide–MHC complexes. CDR3 (also known as junctional) diversity is achieved by multiple mechanisms. These mechanisms include the following:

1. The addition of one or two nucleotides that are palindromic to the end of the cut gene segment (termed P-nucleotides); these nucleotides are added as part of the process of asymmetric repairing of "hairpin" ends (the two strands of DNA are joined at the ends) that are generated by RAG endonuclease activity
2. The activity of terminal deoxytransferase (TdT; also referred to as deoxynucleotidyltransferase terminal), which randomly adds nucleotides (called N-nucleotides) to the ends of segments undergoing rearrangement; TdT addition is a particularly important mechanism for diversity generation because every three additional nucleotides encodes a potential codon, potentially increasing repertoire diversity by a factor of 20
3. Exonuclease activity that results in a variable loss of nucleotide residues, as part of the DNA repair process

Together, the mechanisms for generating diversity can theoretically result in $10^{15}$ types of αβ-TCR. In reality, the final repertoire of naïve T cells in the adult human circulation is on average a total of $10^6$ different TCR β chains, each pairing on average with at least 25 different TCR α chains [438]. This results in a maximum of about $10^8$ different combinations of TCR α and TCR β chains for the naïve T-cell αβ-TCR repertoire. Because in young adults the body has approximately $2 \times 10^{11}$ CD4 T cells and $1 \times 10^{11}$ CD8 T cells [439,440], of which about 50% belong to the naïve subset, the average clonal size (all clones express an identical αβ-TCR) for a naïve T cell is approximately 500 to 1000 [438,441].

RAG expression is present by the double-negative thymocyte stage, with the TCR-γ chain and TCR-δ chain genes typically undergoing rearrangement first [442]. The TCR β gene becomes accessible to RAG proteins before the TCR α gene, and it is the first to undergo rearrangement (a small fraction of double-negative cells may undergo productive rearrangements of the TCR γ and TCR δ genes; this is discussed in more detail in the section on γδ T cells). The TCR β chain D segment first rearranges to a downstream J segment, with the deletion of intervening DNA. This is followed by rearrangement of a V segment to the DJ segment, resulting in a contiguous (VDJ) β chain gene segment, which is joined to the constant (C) region segment by mRNA splicing. If a VDJ segment lacks premature translation stop codons, the TCR β chain protein may be expressed on the thymocyte surface in association with a pre-TCR α chain protein (pre-Tα) and the CD3 complex proteins [443]. This pre-Tα complex signals intracellularly and instructs the thymocyte to increase its surface expression of CD4 and CD8, to start rearrangement of the TCR α chain gene, and to stop rearrangement of the other TCR β chain allele [444]. This inhibition of TCR β chain gene rearrangement results in allelic exclusion, so that greater than 99% of αβ T cells express only a single type of TCR β chain gene [445]. Pre-Tα complex signaling also results in multiple rounds of cell division of the thymocyte [446], which improves the chances that some of the progeny would have a productive TCR-β and TCR-α gene rearrangement.

Rearrangement of the TCR α chain gene occurs at the double-positive stage and involves the joining of V segments directly to J segments, without intervening D segments. If successful, this leads to the expression of a TCR αβ heterodimer on the cell surface in association with CD3 proteins to form the TCR-CD3 complex. Allelic exclusion is ineffective for the TCR α chain gene, and it is estimated that one third of peripheral human αβ T cells may express two types of TCR α chains [447]. RAG protein expression normally ceases in cortical thymocytes, limiting TCR gene rearrangement to thymic development.

## Fetal and Neonatal T-Cell Receptor Repertoire

The generation of the αβ-TCR repertoire by the process of V(D)J recombination of TCR β and TCR α genes probably occurs within a few days after colonization of the thymus by prothymocytes. The usage of D and J segments in rearrangement of the TCR β chain gene in the thymus at approximately 8 weeks of gestation is less diverse than at 11 to 13 weeks of gestation or subsequently [448–450]. This restriction is not explained by an effect of positive or negative selection in the thymus because it applies to D-to-J rearrangements, which are not expressed on the immature thymocyte cell surface [448–451]. The CDR3 region of the TCR β chain transcripts is reduced in length and sequence diversity in the human fetal thymus between 8 and 15 weeks of gestation. This is probably due to decreased amounts of the TdT enzyme, which performs N-nucleotide addition during V(D)J recombination [448–452]. TdT is detectable by 13 weeks of gestation, and fetal TdT activity and CDR3 length increase during the second trimester [448–450].

Exonuclease activity ("nucleotide nibbling"), in which there is variable trimming of the length of V(D)J segments before their joining by Artemis and, possibly, a long isoform of TdT, remains relatively constant from the second trimester onward [452]. Vα and Vβ segment usage in the thymus and peripheral lymphoid organs is diverse [449–451,453]. The αβ-TCR repertoire of cord blood T cells that is expressed on the cell surface is characterized by a diversity of TCR β usage and CDR3 length that is similar to that of antigenically naïve T cells in adults and infants, indicating that the functional preimmune repertoire is fully formed by birth [454–457].

Because the CDR3 region of the TCR chains is a major determinant of antigen specificity [458], decreased CDR3 diversity, in conjunction with restricted usage of V(D)J segments, theoretically could limit recognition of foreign antigens by the fetal αβ-TCR repertoire, particularly during the first trimester. The effects of any potential "holes" in the αβ-TCR repertoire of the human fetus from limitations in CDR3 are likely to be subtle, however, particularly after the second trimester, when V segment usage is diverse. This is suggested by the fact that the T-cell response to immunization and viral challenge generally is normal in mice that are completely deficient in TdT as a result of selective gene targeting [459].

Analysis of the TCR repertoire suggests that there is greater oligoclonal expansion of αβ T cells during the third trimester, particularly after 28 weeks of gestation, than in adults, and that these oligoclonal expansions involve a variety of different Vβ segment families [460]. Whether this oligoclonal expansion is antigen-driven, such as by a response to maternally derived immunoglobulins (e.g., immunoglobulin idiotypes) [461], or, more likely, is a form of homeostatic proliferation is unknown.

## T-CELL RECEPTOR EXCISION CIRCLES

The V(D)J recombination process that joins the TCR gene segments also generates double-stranded circular DNA by-products of the intervening sequences, known as T-cell receptor excision circles (TRECs). TRECs seem to be stable throughout the life of a T-lineage lymphocyte. Because they lack a DNA origin of replication, TRECs are diluted at the population level by cell proliferation [462]. The level of DβJβ TRECs, which are formed during Dβ to Jβ rearrangement of the TCR-β gene locus during the double-negative stage of thymocyte development, is at the highest concentration in this cell population [463].

The marked thymocyte proliferation after surface expression of a TCR-β/pre-Tα complex is indicated by the observation that double-positive thymocytes lacking αβ-TCR/CD3 surface complexes (and have not yet achieved a productive TCR-α gene rearrangement) have only 4% of the concentration of DβJβ TRECs per cell as do double-negative cells [463]; this suggests that about four to five mitoses occur between these two stages of thymocyte development. At the double-positive αβ-TCR/$CD3^-$ stage of thymocyte development, most TCR-α gene loci first undergo a rearrangement that deletes much of the TCR-δ gene locus, which is located between clusters of Vα and Jα segments. This rearrangement forms a signal joint (sj) between the δRec segment and the downstream ψJα segment and a sjTREC that contains the deleted Dδ, Jδ, and Cδ segments (Fig. 4–10); this irreversibly commits the TCR-α/δ gene locus undergoing this rearrangement to the αβ-TCR differentiation pathway [464]. This rearrangement is followed by a second V(D)J recombination event, discussed in the previous section, in which Vα is joined to Jα to form a recombined Vα-Jα-Cα gene segment and a coding joint (cj)TREC.

sjTRECs, which are the result of sj forming between a δRec segment and a downstream ψJα segment in the TCR-α gene (see Fig. 4–10), have been the predominant type of TREC assayed in human studies. In most αβ T cells, both TCR-α/δ gene loci have undergone δRec/ψJα joining, with the maximal theoretical level of sjTREC content per T-lineage cell being 2. The highest levels of sjTRECs that have been measured are 1.5 copies/cell for $CD4^+CD8^+$αβ-TCR/$CD3^-$ human fetal thymocytes [465,466]. As fetal thymocytes progress to the $CD4^+CD8^+CD3^{mid}$ and the mature single-positive ($CD4^+CD8^-CD3^{hi}$ or $CD4^-CD8^+CD3^{hi}$) stages, the sjTREC content declines to 0.7 copies/cell and 0.6 copies/cell [465,466]. This indicates that the maturation of double-positive into single-positive thymocytes, which occurs by the process of positive selection described subsequently, is accompanied by approximately one cell division.

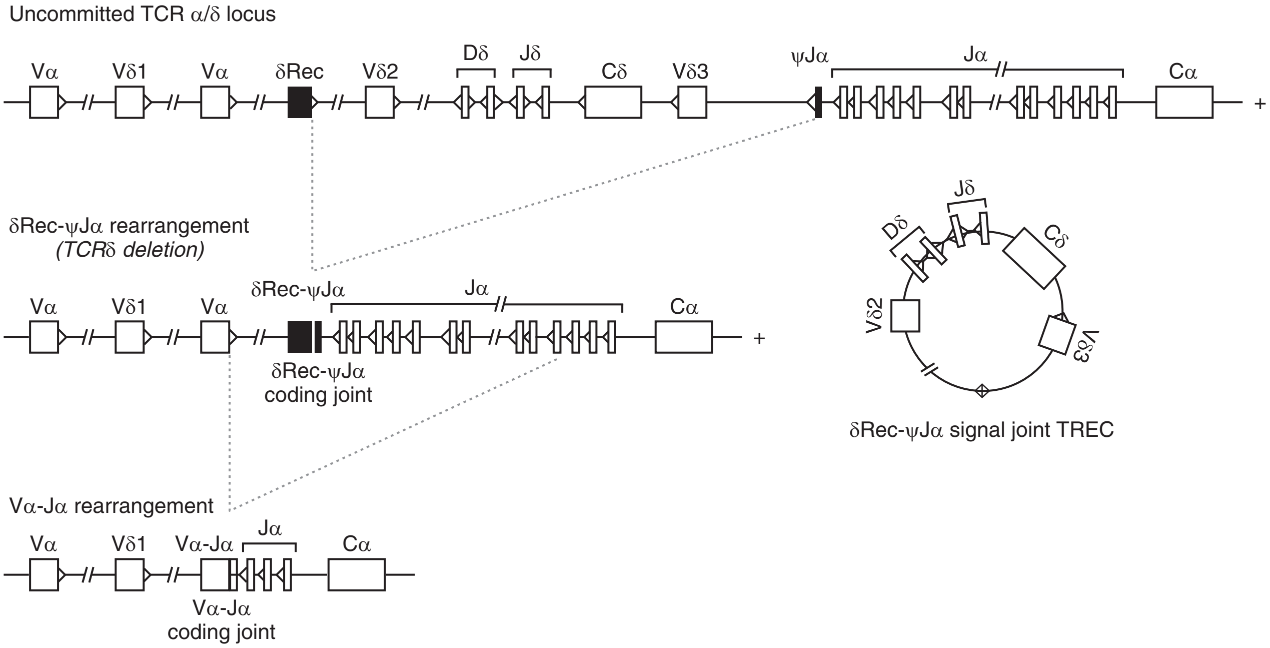

**FIGURE 4–10 Sequential rearrangements in the T-cell receptor (TCR)-α/δ locus generate signal joint T-cell receptor excision circles (sjTRECs) and Vα-Jδ rearrangements.** Rearrangement of δRec to Jα segment results in a commitment to αβ-TCR lineage because this deletes the C and J segments that are necessary to encode a productive TCR-δ chain. δRec-ψJα rearrangement also generates sjTREC, which is commonly used for monitoring peripheral T-cell populations for their recent thymic origin. δRec-ψJα rearrangement is followed by TCR-α (Vα-Jδ) rearrangements, which, if productive, result in expression of αβ-TCR on the thymocyte cell surface. Most thymocytes that express αβ-TCRs have molecular evidence of nonproductive rearrangements of portions of TCR-δ gene locus (*not shown*).

The sjTREC content of neonatal CD4 T cells is significantly higher than adult antigenically naïve CD4 T cells, indicating that a greater fraction of the adult naïve CD4 T-cell subset has undergone cell division, most likely in the form of homeostatic proliferation, than in the neonate. Such homeostatic proliferation, in which the naïve CD4 T cells retain their characteristic surface phenotype (i.e., CD45RA$^{hi}$L-selectin$^{hi}$), seems to occur as PTK7$^{+}$ CD4 RTEs mature into PTK7$^{-}$ naïve CD4 T cells because the sjTREC content of PTK7$^{+}$ CD4 RTEs is significantly higher than that of PTK7$^{-}$ naïve CD4 T cells [433]. The ratio of sjTRECs and DβJβ TRECs (generated during Dβ to Jβ gene segment rearrangement) in peripheral naïve T cells has also been used to infer the relative amount of intrathymic proliferation occurring between the double-negative and double-positive stages of thymic development, with higher values indicating greater amounts of proliferation [463]. In certain states, such as HIV infection, this ratio is reduced in peripheral T cells, indicating that the infection has a deleterious impact on the intrathymic production of T cells [463].

## THYMOCYTE SELECTION AND LATE MATURATION

### Positive and Negative Selection

Thymocytes that have successfully rearranged and express αβ-TCRs have a CD4$^{hi}$CD8$^{hi}$ surface phenotype (see Fig. 4–8) and undergo a selective process that tests the appropriateness of their TCR specificity, known as positive selection [444]. Positive selection requires that the αβ-TCR recognize self-peptides bound to MHC molecules displayed on epithelial cells of the thymic cortex. If the TCR has sufficient, but not too high, affinity for self-peptide–MHC complexes, the thymocyte receives a signal allowing its survival. If this signal is absent or weak, the thymocyte dies by apoptosis as a result of activation of caspases, a family of intracellular cysteine proteases. Too strong a signal in the thymic cortex also may not result in effective positive selection.

Studies indicate that the default pathway of maturation of a positively selected double-positive thymocyte is to become to a mature CD4$^{-}$CD8$^{hi}$ single-positive cell. If the double-positive thymocyte receives a relatively strong signal via the αβ-TCR/CD3 complex, however, this increases the expression of the GATA-3 transcription factor, which induces the ThPOK transcription factor. ThPOK acts to help upregulate its own expression and prevent the loss of CD4 expression by binding to and inhibiting silencer elements in both of these genes [467]. This action directs the double-positive thymocyte to become a CD4$^{hi}$CD8$^{-}$ single-positive cell and ultimately a naïve CD4 T cell. Positive selection also extinguishes *RAG* gene expression, terminating further TCR-α rearrangement. Effective positive selection by MHC class I and MHC class II molecules requires that cortical thymic epithelial cells express the proteolytic enzyme cathepsin L [468] and a novel β5t catalytic subunit of the proteasome [469]. This requirement most likely reflects the importance of generating a specialized set of peptides for positive selection, although the identities of these peptides remain to be defined.

Positively selected CD4$^{hi}$CD8$^{-}$ and CD4$^{-}$CD8$^{hi}$ thymocytes enter the medulla, where they undergo a second

selection process called negative selection, in which they are eliminated by apoptosis if their TCR has too high an affinity for self-peptide–MHC complexes expressed on medullary DCs [470]. Negative selection helps eliminate αβ T cells with TCRs that could pose a risk of autoimmune reactions and is an important influence on the final TCR repertoire. Thymic epithelial cells found in the medulla express a diverse array of tissue-specific self-antigens (e.g., insulin, myelin basic protein) that help in this elimination. Individual thymic medullary epithelial cells express only some of these self-antigen proteins, and this expression is acquired in an apparently stochastic manner.

The protein encoded by the autoimmune regulator (AIRE) gene plays a key role in enhancing the expression of these tissue-specific proteins by thymic epithelial cells. AIRE may act as a transcriptional coactivator that interacts with components of the RNA polymerase to overcome the inhibitory influence of unmethylated histones in the region of the transcriptional start site [471]. The importance of AIRE is indicated by the high frequency of autoimmune endocrine disease in patients with AIRE gene defects, particularly hypoadrenalism, hypoparathyroidism, and type 1 diabetes mellitus. AIRE may play a similar role in inducing peripheral T-cell tolerance by increasing the expression of tissue-specific antigens by lymph node stromal cells. As a net result of the failure to rearrange productively the TCR α or TCR β chain gene, the lack of positive selection, or the occurrence of negative selection, only about 2% to 3% of the progeny of hematopoietic lymphoid precursors that enter the thymus emerge as mature single-positive thymocytes.

Because the region forming the peptide-binding groove of MHC molecules is highly polymorphic in humans (see section on basic aspects of antigen presentation), a result of positive selection is that T cells have a strong preference for recognizing a particular foreign peptide bound to self-MHC, rather than to the MHC of an unrelated person. The fact that TCR has intrinsic affinity for MHC molecules [472] accounts for the ability of an APC bearing foreign MHC molecules to activate a substantial proportion (several percent) of T cells—the allogeneic response. In the allogeneic response, T cells are activated by novel antigen specificities that are thought to result from the combination of a foreign MHC with multiple self-peptides [473]. Because these self-peptide–foreign MHC specificities are not expressed in the thymus, T cells capable of recognizing them have not been eliminated by the negative selection process in the medulla.

### Thymocyte Growth and Differentiation Factors

The factors within the thymic microenvironment that are essential for thymocyte development include key cytokines produced by thymic epithelial cells, such as IL-7. Individuals lacking a functional IL-7 receptor, owing to a genetic deficiency of either the IL-7 receptor α chain or the common γ chain (γc) cytokine receptor (CD132) with which the α chain associates, have abortive thymocyte development and lack mature αβ T cells [437]. A similar phenotype is observed with genetic deficiency of JAK-3 tyrosine kinase, which is associated with the cytoplasmic domain of the γc cytokine receptor and delivers activation signals to the interior of the cell [474]. Human fetal B-cell development is spared in these human genetic immunodeficiencies, although a lack of γc-dependent cytokine receptors, such as that for IL-21, results in these B cells having intrinsic functional defects.

### Thymocyte Postselection Maturation

$CD4^{hi}CD8^{-}$ and $CD4^{-}CD8^{hi}$ thymocytes are the most mature αβ T-lineage cell population in the thymus and predominate in the thymic medulla. Many of the functional differences between peripheral CD4 and CD8 T cells apparently are established during the later stages of thymic maturation, presumably as a result of differentiation induced by positive selection: Mature $CD4^{hi}CD8^{-}$ thymocytes are similar to peripheral CD4 T cells, in that they are enriched in cells that can secrete certain cytokines, such as IL-2, and provide help for B cells in producing immunoglobulin [475,476]. $CD4^{-}CD8^{hi}$ thymocytes are similar to peripheral CD8 T cells, in that they have a relatively limited ability to produce IL-2, but when primed by antigen are effective in mediating cytotoxic activity [475]. In preparation for thymic emigration, the last stages of single-positive thymocyte maturation include increased levels of the Kruppel-like factor 2 (KLF-2) transcription factor, which seems to increase the thymocyte expression of the sphingosine 1-phosphate receptor [477]. Thymocytes are then directed to emigrate into the blood or lymph or both; blood and lymph have high concentrations of sphingosine 1-phosphate compared with the medulla.

## NAÏVE T CELLS

### CD4 and CD8 Recent Thymic Emigrants

Mature $CD4^{hi}CD8^{-}$ and $CD4^{-}CD8^{hi}$ single-positive thymocytes enter into the circulation as RTEs, joining the antigenically naïve CD4 and CD8 αβ T-cell compartments (see Fig. 4–8). In humans, RTEs of the CD4 T-cell lineage are identified by their expression of protein tyrosine kinase 7 (PTK7), a member of the receptor tyrosine kinase family [433]. The function of PTK7 in immune function is unclear (Lewis DB, unpublished observations, 2009), and this protein has no known ligands and seems to be a catalytically inactive kinase because it lacks a functional adenosine triphosphate (ATP) binding cassette in its cytoplasmic domain [478]. Approximately 5% of circulating naïve CD4 T cells from healthy young adults are $PTK7^{+}$, and these cells are highly enriched in their sjTREC content compared with $PTK7^{-}$ naïve CD4 T cells, but otherwise have a similar surface phenotype [433]. As expected for an RTE cell population, $PTK7^{+}$ naïve CD4 T cells have a highly diverse αβ-TCR repertoire similar to that of the overall naïve CD4 T-cell population and rapidly decline in the circulation after complete thymectomy (performed for the treatment of myasthenia gravis) [433]. As described subsequently, $PTK7^{+}$ naïve CD4 T cells (hereafter referred to as $PTK7^{+}$ CD4 RTEs) from healthy adults have reduced activation-dependent function compared with $PTK7^{-}$ naïve CD4 T cells.

Virtually all CD4 T cells and most CD8 T cells of the neonate express high levels of surface protein and mRNA transcripts for PTK7, which is a marker for CD4 RTEs in older children and adults [433] (Lewis DB, unpublished observations, 2009). Although this high level of PTK7 expression by neonatal naïve CD4 T cells may be explained in part by their being highly enriched in RTEs, it is likely that PTK7 expression is regulated differently in neonatal CD4 T cells compared with adult naïve CD4 T cells based on two observations: First, there is a higher level of expression of PTK7 per neonatal naïve CD4 T cell compared with adult PTK7 CD4 RTEs [433]. Second, there are few, if any, PTK7$^-$ cells among circulating neonatal naïve CD4 T cells even though studies of older children undergoing complete thymectomy suggest that most PTK7$^+$ CD4 RTEs are converted to PTK7$^-$ naïve CD4 T cells over a 3-month period [433], and at least some neonatal T cells are likely to have emigrated from the thymus more than 6 months previously.

The expression of CD103 ($\alpha_E\beta_7$ integrin) seems to be a marker for CD8, but not CD4 T-lineage RTEs [466]. As for PTK7$^+$ CD4 RTEs, the thymic dependence of this circulating CD8 RTE population has been shown by the impact of complete thymectomy [466], and these cells are relatively enriched in sjTRECs compared with CD103$^-$ naïve CD4 T cells. It is unclear whether CD103$^+$ naïve CD8 T cells in the adult circulation differ in function from that of the CD103$^-$ naïve CD8 T-cell subset.

## Naïve T-Cell Entry into Lymphoid Tissue, Recirculation, and Survival

Human naïve CD4 T cells have a CD45RA$^{hi}$CD45RO$^{lo}$-CD27$^{hi}$L-selectin$^{hi}\alpha_4\beta_1$–CD11a$^{dim}$ surface phenotype [479]. Naïve T cells, including RTEs, preferentially home to the secondary lymphoid tissue, which includes the lymph nodes, spleen, Peyer patches, and MALT, and then recirculate along with the rest of the antigenically naïve CD4 and CD8 T-cell compartments. Egress of RTEs from the thymus and of naïve T cells and B cells from secondary lymphoid tissue requires that these cell types express sphingosine 1-phosphate receptors. Sphingosine 1-phosphate, the receptor ligand, is at higher concentrations in the blood and lymph than in the thymus and secondary lymphoid tissue, which directs these cells to exit the tissues and enter into these fluids [480]. Bronchus-associated lymphoid tissue, a type of MALT, typically appears only after birth and is another potential site for naïve T-cell homing and recirculation [481].

Development of secondary lymph node tissues depends on signaling by lymphotoxin (LT) α and β members of the TNF cytokine gene family (see Table 4–1). Peripheral lymphoid organogenesis involves lymphoid tissue inducer cells, which are CD45$^+$CD4$^+$CD3$^-$ and express surface LT$\alpha\beta_2$ trimers engaging the LTβ receptor on stromal cells. Stromal cells are induced to become stromal organizers by increasing their expression of adhesion molecules (VCAM-1, ICAM-1, and MAdCAM-1) and of chemokines (CXCL13, CCL19, and CCL21), which attracts naïve B cells and T cells and more lymphoid tissue inducer cells, ultimately resulting in fully formed peripheral lymph nodes [482].

As described for DCs, migration of fully mature naïve T cells and RTEs, both of which express high levels of the CCR7 chemokine receptor and L-selectin [433], into the peripheral lymphoid organs is determined in part by the local patterns and gradients of chemokine receptor ligands in tissues (see Tables 4–1 and 4–2) and ligands for adhesion molecules. L-selectin, which is constitutively expressed on many types of leukocytes, including naïve and certain subsets of memory T cells, binds to multivalent carbohydrate ligands displayed on specific protein or lipid backbones on the cell surface. T-cell surface expression of L-selectin allows their binding to the peripheral lymph node addressin, which is expressed on the surface of the specialized high endothelium of the postcapillary venules in the peripheral lymph nodes, Peyer patches, and tonsils [483]. Tethered to the surface of the high endothelium of the postcapillary venules is the chemokine CCL21, which binds to CCR7 on the surface of RTEs and naïve T cells. CCL21 and another CCR7 ligand, CCL19, are produced by stromal cells and perhaps some APCs in the lymph node. The engagement of CCR7 on naïve T cells by CCL21 triggers signals leading to an increase in the affinity of LFA-1, allowing the naïve T cells to bind avidly to the LFA-1 ligands ICAM-1 and ICAM-2 on the vascular endothelium. This stops T-cell rolling, allowing the T cell to undergo diapedesis across the endothelium and to enter the T-cell zones of the lymph node. CCL19 is produced there by DCs, resulting in the juxtaposition of naïve T cells and DCs [483].

Based on elegant studies in mice, the survival of naïve T cells in the periphery has been shown to be dependent on two major exogenous factors. The first is continuous interaction with self-peptide–MHC complexes, which seems to be particularly important for the survival of the antigenically naïve T-cell populations [484]. Whether this survival signal is analogous to positive selection in the thymus in its requirements for a diverse self-peptide repertoire is unclear. The second major factor seems to be signals provided by IL-7 binding to IL-7 receptors on naïve CD4 and CD8 T cells [484]. It is unclear if human naïve T cells have similar requirements for their survival in the periphery, and, if so, whether RTEs and more mature naïve T cells differ in their dependence on these αβ-TCR/CD3 and cytokine receptor signals.

# ONTOGENY OF NAÏVE T-CELL SURFACE PHENOTYPE

Circulating T cells are detectable by 12.5 weeks of gestation, showing the emigration of mature T-lineage cells from the thymus [485]. By 14 weeks of gestation, CD4 and CD8 T cells are found in the fetal liver and spleen, and CD4 T cells are detectable in lymph nodes [486]. The percentage of T cells in the fetal or premature circulation gradually increases during the second and third trimesters of pregnancy through approximately 6 months of age [486], followed by a gradual decline to adult levels during childhood [487]. The ratio of CD4 to CD8 T cells in the circulation is relatively high during fetal life (about 3.5) and gradually declines with age [487]. The levels of expression of the αβ-TCR, CD3, CD4, CD5, CD8, and

CD28 proteins on fetal and neonatal αβ T cells are similar to those in adult T cells (Lewis DB, unpublished data, 2008) [488].

## CD31

CD31, also known as platelet endothelial cell adhesion molecule-1 (PECAM-1), is expressed in large amounts on most adult peripheral CD4 T cells that have a naïve (CD45RA$^{hi}$) surface phenotype, but is absent or decreased on most memory CD4 T cells. A small fraction of CD45RA$^{hi}$ CD4 T cells that are CD31$^{lo}$ appears and gradually increases with aging, especially after adulthood, and these cells have very low sjTREC content and an oligoclonal rather than polyclonal αβ-TCR repertoire compared with either PTK7$^{+}$ CD4 RTEs (which are uniformly CD31$^{hi}$) or PTK7$^{-}$ CD31$^{hi}$ naïve CD4 T cells [489,490]. It has been argued that these CD31$^{lo}$ naïve CD4 T cells are the result of homeostatic proliferation of CD31$^{hi}$ naïve CD4 T cells, rather than reversion of memory/effector cells to a CD45RA surface phenotype because these cells lack a capacity to express cytokines characteristic of memory/effector cells, such as IFN-γ. The origin of the cells constituting this CD31$^{lo}$ subset might be clarified by more extensive phenotyping, including gene expression profiling.

Most neonatal CD45RA$^{hi}$ T cells are CD31$^{hi}$, but approximately 10% to 20% have been reported to be CD31$^{lo}$ [491]. It is unclear if the neonatal CD31$^{lo}$ subset of naïve CD4 T cells has low levels of sjTRECs similar to that found in adult CD31$^{lo}$ naïve CD4 T-cell subset, which would suggest that these cells have undergone extensive proliferation compared with most neonatal CD4 T cells. Alternatively, a finding of high sjTREC content in CD31$^{lo}$ naïve CD4 T cells of the neonate would suggest that this population may be an immature population that gives rise to CD31$^{hi}$ naïve CD4 T cells. Because neonatal CD4 T cells are uniformly PTK7$^{hi}$, and PTK7 expression by adult CD4 RTEs is lost in an in vitro model of homeostatic proliferation using a cytokine cocktail [433], the latter possibility seems to be more likely.

## CD38

CD38 is an ectoenzyme that generates cyclic adenosine diphosphate (ADP)–ribose, a metabolite that induces intracellular calcium mobilization. It is expressed on most thymocytes, some activated peripheral blood T cells and B cells, plasma cells, and DCs. In contrast adult naïve T cells, virtually all peripheral fetal and neonatal T cells express very high levels of the CD38 molecule [492,493], suggesting that peripheral T cells in the fetus and neonate may represent a thymocyte-like immature transitional population. There is no substantial difference in CD38 expression by adult circulating PTK7$^{+}$ CD4 RTEs and PTK7$^{-}$ naïve CD4 T cells [433], indicating that this persistence of high levels of CD38 expression is unique to the naïve T-cell compartment of the fetus and neonate. In contrast with circulating fetal and neonatal T cells, a significant fraction of T cells in the fetal spleen between 14 and 20 weeks of gestation lack CD38 expression [494], which suggests that CD38 may be downregulated on entry into secondary lymphoid tissue.

As discussed subsequently, a significant fraction of splenic CD4 T cells in the fetus seem to belong to the regulatory T-cell subset, and it is plausible that this subset may have only relatively low levels of CD38 expression, based on analysis of adult regulatory T cells (Tregs) [495]. Neonatal CD4 T cells lose expression of CD38 after in vitro culture with IL-7 for 10 days [496], which implies that this cytokine promotes further maturation independently of engagement of the αβ-TCR–CD3 complex. The precursor-product relationship between CD38$^{+}$ and CD38$^{-}$ peripheral naïve T cells in humans is unclear.

The role of CD38 in the function of human T cells and other cell types also is unknown. In mice, CD38 is required for chemokine-mediated migration of mature DCs into secondary lymphoid tissue, and as a consequence, CD38 deficiency impairs humoral immunity to T-cell–dependent antigens. Mice, in contrast with humans, have relatively low levels of thymocyte expression of CD38, and CD38 deficiency in these animals does not have a clear impact on thymocyte development or intrinsic T-cell function.

## CD45 Isoforms

Circulating T cells in the term and preterm (22 to 30 weeks of gestation) neonate and in the second-trimester and third-trimester fetus predominantly express a CD45RA$^{hi}$CD45RO$^{lo}$ surface phenotype [493,497,498], which also is found on antigenically naïve T cells of adults. About 30% of circulating T cells of the term neonate are CD45RA$^{lo}$CD45RO$^{lo}$ [499], a surface phenotype that is rare or absent in circulating adult T cells. Because these CD45RA$^{lo}$CD45RO$^{lo}$ T cells are functionally similar to neonatal CD45RA$^{hi}$CD45RO$^{lo}$ T cells and become CD45RA$^{mid}$CD45RO$^{lo}$ T cells when incubated in vitro with fibroblasts [499], they seem to be immature thymocyte-like cells, rather than naïve cells that have been activated in vivo to express the CD45RO isoform.

Most studies have found that the healthy neonate and the fetus in late gestation lack circulating CD45RO$^{hi}$ T cells, consistent with their limited exposure to foreign antigens. A lack of surface expression of other memory/effector markers, such as $\beta_1$ integrins (e.g., VLA-4) and, in the case of CD8 T cells, KIRs [500] and CD11b [501,502], also is consistent with an antigenically naïve population predominating in the healthy neonate.

A postnatal precursor-product relationship between CD45RA$^{hi}$CD45RO$^{lo}$ and CD45RA$^{lo}$CD45RO$^{hi}$ T cells is suggested by the fact that the proportion of αβ T cells with a memory/effector phenotype and the capacity of circulating T cells to produce cytokines, such as IFN-γ, gradually increase, whereas the proportion of antigenically naïve T cells decreases, with increasing postnatal age [487,503]. These increases in the ability to produce cytokines and expression of the CD45RO$^{hi}$ phenotype presumably are due to cumulative antigenic exposure and T-cell activation, leading to the generation of memory T cells from antigenically naïve T cells.

In premature or term neonates who are stressed, a portion of circulating T-lineage cells are CD3$^{lo}$ and coexpress CD1, CD4, and CD8 [492], a phenotype characteristic of immature thymocytes of the cortex

[504]. It is likely that stress results in the premature release of cortical thymocytes into the circulation, but the immunologic consequences of this release are unclear.

A few, although still a substantial proportion, T cells in the second-trimester fetal spleen are CD45RA$^{lo}$CD45RO$^{hi}$, a T-cell population that is absent from the spleen of young infants [498]. These fetal CD45RO$^{hi}$ T cells have a diverse αβ-TCR repertoire and express high levels of CD25 (IL-2 receptor α chain) and proliferate with IL-2 [499]. In contrast to adult CD45RO$^{hi}$ T cells, these fetal spleen CD45RO$^{hi}$ T cells express low surface levels of CD2 and LFA-1 and proliferate poorly after activation with either anti-CD2 or anti-CD3 monoclonal antibody (mAb), suggesting that they are not fully functional [498]. As discussed in "Regulatory T Cells of the Fetus and Neonate," many features of this cell population are consistent with their being Tregs, which have been shown to be prominent in the spleen and lymph nodes of the fetus [505,506]. The extent to which these fetal spleen CD45RO$^{hi}$ T cells contribute to the postnatal (Treg or non-Treg) peripheral T-cell compartment is unknown.

# HOMEOSTATIC PROLIFERATION

## Spontaneous Naïve Peripheral T-Cell Proliferation

Naïve T cells may undergo proliferation by processes that are distinct from the processes of full activation by cognate antigen and appropriate costimulation, and such proliferative processes may make a significant contribution to expansion of the peripheral T-cell pool during development. Based on flow cytometric analysis of expression of the Ki67 antigen, a significantly higher fraction of naïve (CD45RO$^{lo}$) CD4 and CD8 T cells in the third-trimester fetus and the term neonate are spontaneously in cell cycle than the fraction of adult naïve T cells [441]. The highest levels are observed at 26 weeks of gestation, and these gradually decline with gestational age. Even at term, the frequencies reported for naïve CD4 and CD8 T cells—approximately 1.4% and 3.2%—are sevenfold those of adult naïve T cells and are substantially higher than the frequencies observed for adult CD45RO$^{hi}$ T cells [441]. These results are supported by other in vitro assays of mitosis, such as the incorporation of tritiated ($^3$H)-thymidine or the loss of fluorescence after labeling cell membranes with carboxyfluorescein succinimidyl ester (CFSE) [507] (Lewis DB, unpublished results, 2008).

A substantial proportion of CD4 and CD8 T cells of the neonate express the killer cell lectin-like receptor G1 (KLRG1) [508], an inhibitory receptor that is also expressed by NK cells and that interacts with cadherins. These KLRG1$^+$ neonatal T cells have naïve surface phenotype, a normal proliferative response to anti-CD3 and CD28 mAb, and a diverse αβ-TCR repertoire, but a reduced sjTREC content compared with their KLRG1$^-$ counterparts [508]. Based on these findings, it is plausible that the KLRG1$^+$ subset of naïve T cells of the neonate may be enriched for cells that have undergone homeostatic proliferation.

Although the mechanism underlying this proliferation of human fetal and neonatal naïve T cells is unclear, it differs from the mechanism in rodent models of homeostatic proliferation, including in the neonatal mouse [509], in that the proliferation occurs in the absence of peripheral lymphopenia. As discussed next, one potential explanation for this increased spontaneous proliferation is an increased sensitivity of fetal and neonatal T cells to cytokines, such as IL-7, which is also a feature of circulating PTK7$^+$ CD4 RTEs of adults [433]. Future studies are needed to determine if spontaneously proliferating naïve T cells in fetus and neonate (and proliferating PTK7$^+$ CD4 RTEs in adults) have a diverse TCR repertoire (as would be predicted by a model of generalized increased sensitivity to cytokines), and whether they can be distinguished from noncycling cells by other markers, such as those that are induced during naïve T-cell proliferation in the setting of peripheral lymphopenia, and by reduced sjTREC content.

## Antigen-Independent Naïve T-Cell Proliferation in Response to IL-7 and IL-15

Murine studies show that the homeostatic proliferation in the lymphopenic host and survival of naïve CD4 and CD8 T cells depends on IL-7 [434]. Human neonatal naïve CD4 T cells are capable of higher levels of polyclonal cell proliferation than adult naïve CD4 T cells in response to IL-7 [441,510-512]; it is plausible that IL-7–dependent proliferation could account for the high rate of spontaneous CD4 T-cell proliferation in the human fetus and neonate and contribute to the normal and rapid expansion of the peripheral CD4 T-cell compartment at this age. The increased IL-7 proliferative response is associated with increased expression of the CD127 (IL-7 receptor α chain component) by neonatal naïve CD4 T cells compared with adult naïve CD4 T cells [510,512,513], although surface expression of the other component of the IL-7 receptor, the γc cytokine receptor, was decreased on neonatal naïve CD4 T cells compared with adult naïve T cells in one study [512]. This increased expression of the IL-7 receptor α chain by neonatal naïve CD4 T cells is not observed for PTK7$^+$ CD4 RTEs in adults [433], indicating that the increased responsiveness of RTEs to IL-7 may be mediated by a different mechanism (see next).

Murine studies also indicate that positive selection results in a dramatic upregulation of the IL-7 receptor α chain and the γc cytokine receptor on CD3$^{hi}$ (mature) CD4–single-positive and CD8–single-positive thymocytes [513]. In vitro thymic organ culture experiments suggest that IL-7 plays a key role in the postselection expansion of the single-positive thymocyte population by a mechanism that does not involve αβ-TCR engagement [513]. Human CD4–single-positive thymocytes have also been shown to have an increased proliferative response to IL-7 [514], suggesting that this increased IL-7 sensitivity also applies to late thymocyte maturation in humans. These observations, taken with the finding that human PTK7$^+$ CD4 RTEs also have an increased proliferative response to IL-7 compared with PTK7$^-$ naïve CD4 T cells even though there are no differences in surface expression of either component of the IL-7 receptor [433] (Lewis DB, unpublished observations, 2009), suggest that the mechanism for this increased

IL-7 sensitivity by neonatal CD4 T cells is (1) likely to be downstream of cytokine receptor binding and (2) shared with mature $CD4^+CD8^-$ thymocytes and $PTK7^+$ CD4 RTEs.

Whether IL-7 not only contributes to extrathymic expansion of naïve CD4 T cells, but also influences their maturation is unclear. IL-7 treatment of neonatal naïve CD4 T cells for relatively long periods (7 or 14 days) does not decrease expression of CD45RA or L-selectin and does not increase the expression of CD45RO [496,510,515,516]. The extent to which IL-7 treatment, alone, of neonatal naïve CD4 T cells results in acquisition of a phenotype with selective features of naïve and memory/effector cells remains contentious: Results are conflicting regarding whether IL-7 treatment increases surface expression of CD11a, a memory/effector cell marker; the activation-dependent proteins CD25 and CD40 ligand; or the capacity of neonatal CD4 T cells to produce $T_H1$ and $T_H2$ cytokines [496,510]. IL-7 in combination with a cocktail of other cytokines (IL-6, IL-10, IL-15, and TNF-α) has been shown to result in the loss of PTK7 surface expression by adult $PTK7^+$ CD4 RTEs, but it is unknown if PTK7 downregulation is accompanied by an increased capacity for $T_H1$ effector function by adult RTEs and if this downregulation occurs with such treatment of neonatal T cells.

Naïve CD4 and CD8 T-cell survival in adults requires interactions between the αβ-TCR and self-peptide/MHC molecules on immature DCs and engagement of the T-cell IL-7 receptor by IL-7 on fibroblastic reticular cells found in the T-cell zone of secondary lymphoid organs; IL-15 may also play a role in CD8 T-cell survival [484]. Human neonatal naïve CD8 T cells are more responsive to treatment with a combination of IL-7 and IL-15 than is the analogous adult cell population, as indicated by loss of CFSE staining with culture after in vitro labeling [441]. Whether this enhanced effect is related to increased levels of IL-15 receptors on neonatal T cells is unknown. Also unclear are the effects of treatment with this combination of cytokines on neonatal naïve CD8 T-cell phenotype and function.

## NAÏVE T-CELL ACTIVATION, ANERGY, AND COSTIMULATION

If naïve T cells encounter DCs presenting cognate peptide–MHC complexes, they stop migrating and remain in the lymph node. If they do not encounter such DCs, they migrate through the lymph node to the efferent lymph and return to the bloodstream. Naïve T cells continually circulate between the blood and secondary lymphoid tissues, allowing them the opportunity to sample APCs continuously for their cognate antigen. Because they regulate this homeostatic recirculation of naïve T cells, CCL19 and CCL21 are referred to as homeostatic chemokines.

When naïve CD4 T cells first encounter foreign peptide–MHC complexes during a primary immune response, they extinguish expression of LKLF, a transcription factor that maintains naïve T cells in a resting state [517], allowing them to become activated. The TCR-CD3 complex is linked to an intricate and highly interconnected complex of kinases, phosphatases, and adapter molecules that together transduce signals in response to engagement of the TCR and, in αβ T cells, the appropriate CD4 or CD8 coreceptor by cognate peptide–MHC complexes (Fig. 4–11; see also Fig. 4–6) [518]. Lipid rafts play a crucial role in facilitating the assembly of signaling complexes at specific regions of the plasma membrane at high local concentrations; these complexes

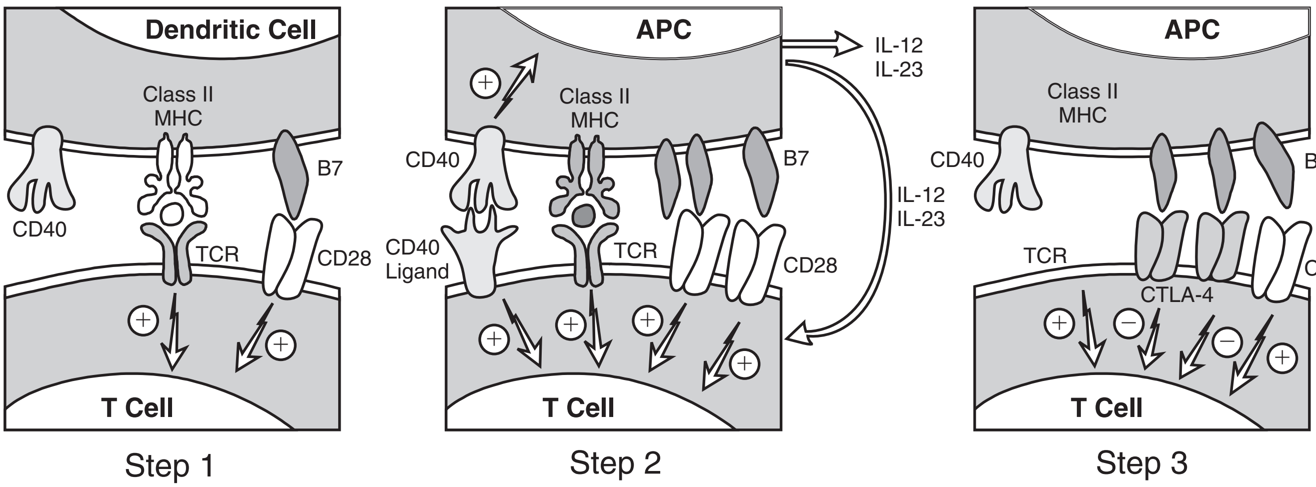

**FIGURE 4–11** **T cell–antigen-presenting cell (APC) interactions early during the immune response to peptide antigens.** Major histocompatibility complex (MHC) class II–restricted response by $CD4^+$ T cells is shown as an example. Dendritic cells are probably the most important APC for antigenically naïve T cells and constitutively express CD80 or CD86 (B7 molecules), CD40, and MHC class II molecules on their cell surface. Engagement of αβ T-cell receptor (αβ-TCR) on the $CD4^+$ T cell by antigenic peptides bound to MHC molecules on the dendritic cell, in conjunction with costimulation by B7 (CD80/86) interactions with CD28 interactions, leads to T-cell activation (*Step 1*). The activated T cell expresses CD40 ligand (CD154) on its surface, which engages CD40 on the dendritic cell; this increases B7 expression on the dendritic cell, enhancing T-cell costimulation (*Step 2*). CD40 engagement also activates the dendritic cell to produce cytokines, such as interleukin (IL)-12. IL-12 promotes the proliferation and differentiation of T cells into $T_H1$-type effector cells that produce high levels of interferon (IFN)-γ and low or undetectable amounts of IL-4. CTLA-4 (CD152) is expressed on T cells during later stages of T-cell activation. Engagement of CTLA-4 by B7 molecules on the APC delivers negative signals that help terminate T-cell activation (*Step 3*).

contained in lipid microdomains recruit adapters and signal-transducing proteins [519]. Proximal activation events include the activation of the Lck and ZAP-70 tyrosine kinases and phospholipase C followed by elevation of inositol triphosphate, which leads to the release of calcium into the cytoplasm from the endoplasmic reticulum. This increase in $[Ca^{2+}]_i$ is sensed by the STIM1 protein of the endoplasmic reticulum, which interacts with and opens calcium-release activated calcium channels of the cell membrane, resulting in a 10-fold increase in $[Ca^{2+}]_i$ and full T-cell activation [520].

An increased calcium concentration activates calcineurin, allowing the translocation of nuclear factor of activated T cells (NFAT) transcription factors from the cytosol to the nucleus. Concurrent activation of the extracellular signal-regulated kinase/mitogen-activated protein kinase (ERK/MAPK) pathway enhances activation of other transcription factors, including activator protein-1/activating transcription factor. T-cell activation also activates the NFκB transcription factor by a pathway that involves protein kinase C-θ and the CARMA1/Bcl10/Malt1 trimolecular complex [518]. Collectively, these transcription factors induce the transcription of genes encoding key proteins for activation, such as cytokines (e.g., IL-2); cell cycle regulators; and, in cytotoxic T cells, proteins involved in killing other cells, such as perforins.

Full naïve T-cell activation that leads to cytokine production and cell proliferation requires that signaling through the trimolecular αβ-TCR–peptide–MHC complex exceed a specific threshold and costimulatory signaling pathways. Low-affinity interactions that do not trigger full T-cell activation, particularly in the absence of costimulation, may lead to a state of long-term unresponsiveness to subsequent stimulation, which is referred to as anergy. Anergy may help maintain tolerance by mature T cells to certain self-antigens—in particular, self-antigens that are not expressed in the thymus in sufficient abundance to induce negative selection. A more recent study suggests that anergy may be the result of activation of caspase 3 and the cleavage by that enzyme of intracellular signaling molecules required for T-cell activation (e.g., Vav1 and adapter molecules) [521], rendering the T cell unresponsive to subsequent encounters with optimal amounts of peptide–MHC antigen complexes and costimulatory molecules.

The best-characterized costimulatory signal is provided by the engagement of CD28 on the T cell with CD80 (B7-1) or CD86 (B7-2) on APCs (see Table 4–4) [522]. CD80 and CD86 are related proteins that are expressed at low levels on immature DCs, mononuclear phagocytes, and B cells and increased levels after LPS exposure, B-cell receptor cross-linking, and CD40 signaling (see Fig. 4–11). APCs primed by these factors and, in particular, mature DCs express high levels of CD80 and CD86. CD80 and CD86 bind to CD28, which is constitutively expressed on T cells, reducing the strength or duration of TCR signaling needed for full activation [522]. Another B7 family member, inducible costimulator (ICOS)–ligand and its receptor on T cells, ICOS, which is homologous to CD28, are important for driving the differentiation of activated T cells into specialized effector lineages, such as $T_H17$ cells and T follicular helper cells ($T_{FH}$), which are discussed in more detail subsequently. Other members of the family such as PD-1 ("programmed death-1") and PD-2 when engaged on the T cell by PD-ligands act to dampen the T-cell response by inducing T-cell apoptosis [522].

Activated T cells are induced to express high-affinity IL-2 receptor complexes composed of the IL-2R α and β chains and γc. Engagement of the IL-2 receptor complex by IL-2, acting as an autocrine and a paracrine growth factor, triggers T cells to undergo multiple rounds of proliferation, expanding the numbers of antigen-specific T cells, and to differentiate into effector T cells (Fig. 4–12). IL-2–mediated proliferation leads to an expansion in the numbers of the responding T-cell population, which is a key feature of antigen-specific immunity. In the absence of prior exposure, the frequency of T lymphocytes capable of recognizing and responding to that antigen is small, generally less than 1:100,000, but in response to infection can increase to greater than 1:20 for CD8 T cells and greater than 1:1000 for CD4 T cells in less than 1 week [523].

Activated T cells, especially those of the CD4 T-cell subset, also express on their surface CD40 ligand (CD154 or TNFSF5), a member of the TNF ligand family (see Tables 4–1 and 4–4) that engages the CD40 molecule on B cells, DCs, and mononuclear phagocytes [524,525]. As mentioned previously, CD40 engagement induces the expression of CD80 and CD86 on these APCs and induces DCs to produce IL-12 family heterodimeric cytokines, such as IL-12p70 (see Fig. 4–11). Interactions between CD40 and CD40 ligand seem to play an important role in vivo in the expansion of CD4 T cells during a primary immune response, but may be less crucial for expansion of CD8 T cells. Several other members of the TNF ligand family can be expressed on activated T cells and may stimulate APC function by binding to their cognate receptors. Activation-induced expression of TNF ligand family members on naïve T cells can amplify the primary immune responses by priming the function of APCs. CD40-ligand/CD40 interactions are also essential for the generation of memory CD4 T cells of the $T_H1$ type (capable of producing IFN-γ, but not IL-4), memory B cells, and immunoglobulin isotype switching [524,525].

## Neonatal T-Cell Activation, Costimulation, and Anergy

Neonatal CD4 T cells, which are virtually all antigenically naïve, and naïve CD4 T cells from adults have comparable IL-2 protein and mRNA expression and rates of IL-2 gene transcription if strong (and potentially nonphysiologic) activators of T cells are used, such as calcium ionophores or mitogenic lectins combined with phorbol esters [526–528]. Neonatal T cells also produce IL-2 and proliferate as well as adult T cells in response to anti-CD3 mAb if optimal CD28 costimulation is provided [529], indicating that CD28-mediated signaling is intact. Decreased IL-2 production by neonatal T cells has been observed using more physiologic activation conditions, however. Compared with adult naïve CD4

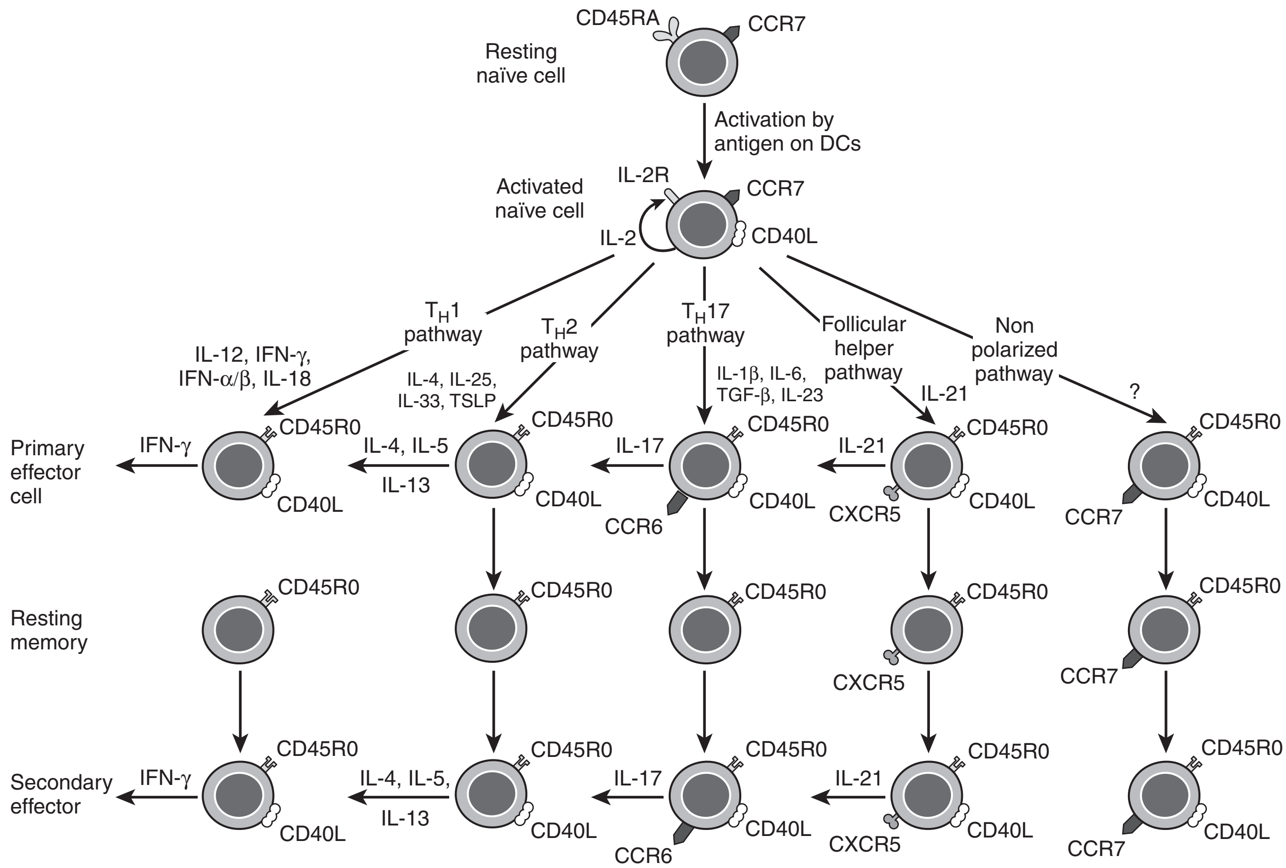

**FIGURE 4–12 Differentiation of antigenically naïve CD4⁺ T cells into $T_H1$, $T_H2$, unpolarized, and T follicular helper effector and memory T cells.** Antigenically naïve CD4⁺ T cells express high levels of the CD45RA isoform of the CD45 surface protein tyrosine phosphatase. They are activated by antigen presented by APC to express CD40-ligand and IL-2 and to undergo clonal expansion and differentiation, which is accompanied by expression of the CD45RO isoform and loss of the CD45RA isoform. Most effector cells die by apoptosis, but a small fraction of these cells persist as memory cells that express high levels of CD45RO. Exposure of expanding effector cells to IL-12, interferon (IFN)-γ, and type I interferon favors their differentiation into $T_H1$ effector cells that secrete IFN-γ, whereas exposure to IL-4 and dendritic cells that have been exposed to thymic stromal lymphopoietin (TSLP), IL-25, and IL-31 favors their differentiation into $T_H2$ effector cells that secrete IL-4, IL-5, and IL-13. Many memory cells are nonpolarized and do not express either $T_H1$ or $T_H2$ cytokines. They may be enriched for cells that continue to express the CCR7 chemokine receptor, which favors their recirculation between the blood and the lymph nodes and spleen. T follicular helper cells, which express high levels of CXCR5, move into B-cell follicle areas where they express CD40 ligand and provide help for B-cell responses. The signals that promote the accumulation of memory T follicular helper cells and their capacity to produce cytokines are poorly understood. Memory cells rechallenged with antigen undergo rapid clonal expansion into secondary effector cells that mediate the same functions as the initial memory population. Most secondary effector cells eventually die by apoptosis.

T cells, neonatal naïve CD4 T cells produced less IL-2 mRNA and expressed fewer high-affinity IL-2 receptors in response to stimulation with anti-CD2 mAb [530–532].

These differences were abrogated when phorbol ester, which bypasses proximal signaling pathways and directly activates the Ras signaling pathway, was included [530], suggesting that the capacity to express IL-2 and high-affinity receptors is not absolutely limited for neonatal cells, but signals leading to their induction may not be transmitted efficiently. Similarly, the production of IL-2 by neonatal naïve CD4 T cells was reduced compared with production by adult CD45RA$^{hi}$ CD4 T cells after allogeneic stimulation with adult moDCs, a system that closely mimics physiologic T-cell activation by foreign peptide/self-MHC complexes [533]. Together, these observations argue that neonatal cells may be intrinsically limited in their ability to be physiologically activated for IL-2 production.

The ability of activated T cells to divide efficiently in response to IL-2 depends on the expression of the high-affinity IL-2 receptor, which consists of CD25 (IL-2 receptor α chain), β chain (shared with the IL-15 receptor), and the γc cytokine receptor (shared with the specific receptors for IL-4, IL-7, IL-9, IL-15, and IL-21). In contrast with IL-2 production, neonatal T cells seem to express similar or higher amounts of CD25 after stimulation with anti-CD3 mAb [526]. This finding is consistent with the signal transduction pathways leading to the induction of CD25 being distinct from the pathways involved in IL-2 production, and with neonatal T cells having a relatively selective limitation in signals required for cytokine production, rather than a generalized limitation acting at an early step of the activation cascade. Basal expression of the γc cytokine receptor by neonatal T cells is lower than that by either adult CD45RA$^{hi}$ or CD45RO$^{hi}$ T cells [534]. The importance

of this finding is unclear because activated neonatal T cells proliferate in response to exogenous IL-2 as well as or better than adult T cells, as indicated by $^3$H-thymidine incorporation [526]. Radioactive thymidine incorporation assays do not provide mitotic information at the single cell level, however, and examine only DNA synthesis and not actual cell proliferation. The application of other techniques, such as cell membrane staining with CFSE [507], which allows an assessment of the mitotic history of individual cells, should be helpful in defining better the replicative potential of neonatal T cells.

Two in vitro studies [535,536] suggest that neonatal T cells may also be less able to differentiate into effector cells in response to neoantigen. One study, using limiting dilution techniques and circulating mononuclear cells from CMV-nonimmune donors, found that the frequency of neonatal T cells proliferating in response to whole inactivated CMV antigen was significantly less than that of adult T cells [535]. A pitfall of this study is that it used a complex antigen preparation and one to which the T cells of adults might have previously been primed by infections other than CMV. Another study [536] found that neonatal mononuclear cells had decreased antigen-specific T-cell proliferation and IL-2 production in response to a protein neoantigen, keyhole limpet hemocyanin, compared with those in adult cells. Although these results require confirmation, they are consistent with the more limited ability of neonatal naïve CD4 T cells to produce IL-2 in response to allogeneic DCs than that of adult naïve cells [533].

Superantigens activate T cells by binding to a portion of the TCR β chain outside of the peptide antigen recognition site, but otherwise mimic activation by peptide–MHC complexes in most respects. Neonatal T cells differ from adult naïve CD45RA$^{hi}$ T cells in their tendency to become anergic rather than competent for increased cytokine secretion after priming with bacterial superantigen bound to MHC class II–transfected murine fibroblasts [537]. This anergic tendency is developmentally regulated because CD4$^{hi}$CD8$^{-}$ thymocytes, the immediate precursors of antigenically naïve CD4 T cells, also are prone to anergy when treated under these conditions [538]. Consistent with this anergic tendency, newborns with toxic shock syndrome–like exanthematous disease, in which the Vβ2-bearing T-cell population is markedly expanded in vivo by the superantigen TSST-1, have a greater fraction of anergic Vβ2-bearing T cells than is found in adults with TSST-1–mediated toxic shock syndrome [539].

Some studies also have found that neonatal, but not adult, CD4 T cells primed by alloantigen, in the form of EBV-transformed human B cells, become nonresponsive to restimulation by alloantigen or by a combination of anti-CD3 and anti-CD28 mAbs [385,540]. Preliminary studies implicate a lack of Ras signaling as the basis for this reduced responsiveness [540]. These results, taken with results using bacterial superantigen, suggest that neonatal and, presumably, fetal T cells have a greater tendency to become anergic, particularly under conditions in which production of inflammatory mediators or costimulation (e.g., by CD40, CD80, or CD86 on the APC) may be limited.

ICOS expression by circulating neonatal and adult CD4 T cells has been reported to be similar [541], but it is unclear if neonatal CD4 T cells are as responsive to signals after ICOS-ligand engagement as adult CD4 T cells (i.e., for the differentiation into $T_H17$ and $T_{FH}$ cells, which are discussed next). There is also limited information on the expression of PD and PD-ligand proteins on neonatal T cells.

## DIFFERENTIATION OF ACTIVATED NAÏVE T CELLS INTO EFFECTOR AND MEMORY CELLS

### Effector CD4 T-Cell Subsets Are Defined by Their Patterns of Cytokine Production

Fully activated naïve CD4 T cells differentiate into effector cells, which have a CD45RA$^{lo}$CD45RO$^{hi}$ surface phenotype and increased expression of adhesion molecules, such as CD11a [542]. The functions of effector T cells, particularly cells of the CD4 subset, are mediated in large part by the multiple additional cytokines they produce that are not produced by naïve T cells. Most of these cytokines are secreted, although some (e.g., some members of the TNF ligand family) may be predominantly expressed on the T-cell surface. These cytokines include IL-3, IL-4, IL-5, IL-9, IL-10, IL-13, IL-17A, IL-17F, IL-21, IL-22, IFN-γ, GM-CSF, CD40 ligand, TNF-α, and Fas-ligand [543,544].

Table 4–2 summarizes the major immunomodulatory effects of T cell–derived cytokines and of cytokines produced by other cell types that act on T cells. IFN-γ is the signature cytokine produced by $T_H1$ effector cells, which also produce substantial amounts of IL-2, lymphotoxin-α, and TNF-α, but little or no IL-4, IL-5, IL-13, IL-17, or IL-21. By contrast, IL-4 is the signature cytokine of $T_H2$ cells, which also produce IL-5, IL-9, and IL-13, but little or no IFN-γ, IL-2, IL-17, or IL-21. Human $T_H17$ cells secrete IL-17A and IL-17F, two members of the IL-17 family. A minor subset of human $T_H17$ cells expresses IL-22 and IFN-γ; in contrast to murine $T_H17$ cells, most human $T_H17$ cells express TNF-α, but not IL-6 [545]. $T_{FH}$ are particularly efficient producers of IL-21, a cytokine that may also be involved in their generation from naïve CD4 T cells [546]. Cells producing effector cytokines of $T_H1$ and $T_H2$ types are commonly referred to as $T_H0$ cells, which often are seen after vaccination with protein antigens or after viral infections, such as influenza virus or CMV [547]. The generation of $T_H0$ cells in vitro seems to be favored by the presence of large amounts of IL-2 in the absence of cytokines that polarize differentiation toward particular effector cell subsets. Most circulating adult memory CD4 T cells seem to be nonpolarized (i.e., not belonging to the $T_H1$, $T_H2$, $T_H17$, or $T_{FH}$ subsets) based on their capacity for cytokine expression and their expression of chemokine receptors [548]. These nonpolarized memory cells can likely give rise to more polarized cell subsets with appropriate instructional signals, which are described subsequently.

In addition to their differing cytokine profiles, the four effector subsets differ in their repertoire of chemokine receptors, and this has an important influence on their

localization and function in vivo. Human $T_H1$ cells preferentially express CCR5 and CXCR3. In contrast, most $T_H2$ cells express CCR4, but only a few $T_H1$ cells do [548]. The expression of CCR5 by most $T_H1$ cells and monocytes allows these two cell types to be concurrently recruited to sites of inflammation [549], which may enhance the activation of mononuclear phagocytes by $T_H1$-derived IFN-γ. The ligands for CCR4, CCL17, and CCL22 are commonly expressed by leukocytes at sites of allergic disease, which attracts $T_H2$ cells that contribute to allergic pathogenesis. Most human $T_H17$ cells express CCR6 [545], which helps target these cells to tissues, such as inflamed gastrointestinal epithelium that produce high levels of CCL20, the sole ligand for CCR6 [550]. $T_{FH}$ cells are defined by their expression of CXCR5, whose sole ligand is CXCL13, a chemokine produced by stromal cells of the B-cell follicle. This CXCR5/CXCL13 interaction helps retain $T_{FH}$ in the B-cell follicles where they can provide help for antibody production [551].

## Regulation of CD4 Effector T-Cell Subset Differentiation

The cytokine milieu encountered by activated naïve CD4 T cells and the key master transcriptional regulatory factors this milieu induces play a dominant role in directing $T_H$ subset differentiation [312]. $T_H1$ effector development is favored by the exposure to high levels of IL-12p70 and IL-18 produced by APCs and to IFN-γ produced by NK cells and other T cells (see Fig. 4–6) and the induction of the T-bet transcription factor. In humans, but less so in mice, type I IFNs also promote $T_H1$ differentiation, although they cannot replace IL-12 in this process [552]. The importance of these cytokines in the development of robust $T_H1$ responses is shown by the limited $T_H1$ responses observed in patients with defects of IL-12 or IL-12 receptor signaling [553,554]. $T_H2$ development is favored when CD4 T cells initially are activated in the presence of IL-4, TSLP, IL-25, and IL-33 (an IL-1 family member), which are derived from epithelial sources [555], particularly in the absence of IL-12, IL-18, type I IFNs, or IFN-γ (see Fig. 4–12). The usual source of IL-4 in this context is uncertain. GATA-binding protein–3 is a master regulator of $T_H2$ T-cell development [312]. $T_H17$ cell development is favored by exposure to IL-1β, IL-6, and TGF-β and IL-21, IL-23, and TNF-α [556], and requires RORγt and RORα as master transcriptional regulators. $T_{FH}1$ cell development in mice, and likely in humans, depends on IL-21 binding to IL-21 receptors on activated naïve CD4 T cells and on ICOS/ICOS-ligand interactions between CD4 T cells and B cells [546]. The transcriptional regulation of $T_{FH}$ differentiation is less well characterized than for the other $T_H$ effector subsets, but c-Maf may play a role in promoting $T_{FH}$ and $T_H17$ development, at least in mice, by increasing IL-21 production [557].

## CD4 T-Cell Help for Antibody Production

CD4 T cells play a crucial role in the regulation of B-cell proliferation, immunoglobulin class switching, affinity maturation, and memory B-cell generation in response to proteins or protein conjugates. The enhancement of B-cell responses is commonly referred to as T-cell help. This process is critically dependent on the recognition through the αβ-TCR of cognate peptide–MHC complexes on B cells, and on multiple contact-dependent interactions (see Fig. 4–11) between members of the TNF ligand–TNF receptor families (see Table 4–1) and the CD28-B7 families (see Table 4–4). Recently activated CD4 T cells that express CXCR5 migrate to B-cell follicles and provide key help for antibody production as $T_{FH}$ cells that secrete IL-21 and express surface CD40 ligand (see Fig. 4–12) [551]. CXCR5 is the receptor for CXCL13 (BCA-1), a chemokine produced by stromal cells of the B-cell follicle. The function of these $T_{FH}$ cells in providing B-cell help is discussed in more detail in the section on naïve B-cell activation, clonal expansion, immune selection, and T-cell help.

The importance of cognate T-cell help is illustrated by the phenotype of patients with X-linked hyper-IgM syndrome, who have genetic defects in the expression of CD40 ligand [525]. In affected individuals, the marked paucity of immunoglobulin isotypes other than IgM and inability to generate memory B-cell responses indicate that these responses critically depend on the engagement of CD40 on B cells by CD40 ligand (CD154) on T cells. Engagement of CD40 on B cells in conjunction with other signals provided by cytokines, such as IL-4 and IL-21, markedly enhances immunoglobulin production and class switching and B-cell survival [558].

Activated and memory CD4 T cells also express ICOS, a receptor for ICOS-ligand, which is constitutively expressed on B cells and various other cell types. ICOS costimulates the T-cell response and promotes the development of $T_H2$ and $T_{FH}$ responses. ICOS-ligand engagement on the B cell by ICOS also is important for enhancing the production of IgG. The identification of ICOS deficiency as a cause of common variable immunodeficiency, in which there is profound hypogammaglobulinemia and poor antibody responses to vaccination [559], shows the importance of ICOS–ICOS-ligand interactions in humans. Other interactions, such as between LFA-1 and CD54 (ICAM-1), may enhance T cell–dependent B-cell responses [560], an idea supported by the finding that humans with CD18 deficiency, which is a component of the LFA-1 integrin, have depressed antibody responses after immunization [561].

Soluble cytokines produced by activated T cells influence the amount and type of immunoglobulin produced by B cells. Experiments in mice in which the IL-2, IL-4, IL-5, or IFN-γ gene or, in some cases, their specific receptors and associated STAT signaling molecules have been disrupted by gene targeting suggest that these cytokines are important for the proper regulation of B-cell immunoglobulin isotype expression. Inactivation of the IL-4 gene, components of the high-affinity IL-4 receptor, or the STAT-6 protein involved in IL-4 receptor signal transduction results in a greater than 90% decrease in IgE production, whereas the production of other antibody isotypes is largely unperturbed [562]. IL-21 secretion by T cells may be important for immunoglobulin production by B cells not only because of direct effects

on B-cell antibody secretion, but also because of IL-21 promoting $T_{FH}1$ development in an autocrine or paracrine manner [546].

## Overview of Memory T Cells

Although greater than 90% of antigen-specific effector T cells generated during a robust primary immune response die, a fraction of effector cells persist as memory T cells. Memory T cells account for the enhanced secondary T-cell response to subsequent challenge—this reflects the substantially greater frequency of antigen-specific memory T cells (approximately 1:100 to 1:10,000) compared with antigen-specific T cells in a naïve host (approximately 1:100,000 for most antigens) and the enhanced functions of memory T cells compared with naïve T cells [563]. Memory T cells retain many of the functions of the effector T cells that characterized the immune response from which the memory T cells arose. These functions include a reduced threshold for activation and the ability to produce more rapidly the effector cytokines that characterized the effector T-cell subset from which they arose (i.e., $T_H1$, $T_H2$, $T_H17$, or $T_{FH}$ cells). Turnover of human memory T cells occurs slowly, but more rapidly than turnover of naïve T cells [563]. Memory T cells apparently persist (in humans most likely for decades) in the absence of further contact with foreign antigenic peptide–MHC complexes [484].

Murine experiments indicate that memory CD4 T cells are derived from a small subset of effector T cells that survive and persist [564]. An origin from effector cells is consistent with the estimation that human memory T cells arise from naïve T-cell precursors after an average of 14 cell divisions as assessed based on telomere length [565], which shortens with lymphocyte cell division [566]. One model proposes that effector and memory T-cell lineages may be generated from the two progeny of a single cell division of an activated naïve CD4 or CD8 T cell because the two daughter cells have unequal partitioning of the proteins involved in cell signaling, cell differentiation, and the asymmetric cell division process itself [567]. Humans genetically deficient in CD40 ligand have reduced CD4 T-cell recall responses to previously administered protein vaccines [568,569], indicating that CD40–CD40 ligand–mediated signals are most likely essential for memory CD4 T-cell generation or maintenance or both.

Similar to effector cells, most human memory CD4 T cells can be distinguished from naïve cells by their surface expression of the CD45RO rather than the CD45RA isoform of CD45 (see Fig. 4–12) [563]. In addition, memory and effector T cells typically express higher levels of adhesion molecules, such as the $\alpha_4\beta_1$ and CD11a/CD18 integrins, than levels observed on naïve T cells (see Table 4–4) [542,570]. About 40% of circulating adult CD4 T cells have this $CD45RA^{lo}CD45RO^{hi}$ ($\alpha_4\beta_1{}^{hi}$) memory/effector surface phenotype, and a fraction of these cells are L-selectin$^{hi}$, most of which belong to the central memory cell subset [571] (discussed subsequently). In persistent viral infection, a subset of memory CD4 T cells expresses PD-1, and this expression is associated with impaired T-cell function in cases of HIV-1 infection.

Activation and propagation of $CD45RA^{hi}CD45RO^{lo}$ CD4 T cells in vitro results in their acquisition of memory/effector cell–like features, including a lower threshold for activation; a $CD45RA^{lo}CD45RO^{hi}$ phenotype in most cases; an enhanced ability to produce effector cytokines (e.g., IFN-γ, IL-4, IL-17, or IL-21); and an increased ability to provide help for B-cell antibody production. These findings support the notion that $CD45RA^{hi}$ T cells are precursors of $CD45RO^{hi}$ T cells and that this differentiation occurs after T-cell activation; in addition, these findings are consistent with the observation that the $CD45RA^{lo}CD45RO^{hi}$ cell subset consists mainly of memory T cells that respond to recall antigens [563].

Memory CD8 T cells are similar to T cells of the CD4 subset in expressing a $CD45RA^{lo}CD45RO^{hi}$ surface phenotype and in possessing an enhanced capacity to produce multiple cytokines compared with that in their naïve precursors and molecules involved in cell-mediated cytotoxicity, such as perforins and granzymes [572]. In addition, in contrast to memory CD4 T cells, a substantial subset of these $CD45RO^{hi}$ CD8 T cells expresses CD11b, CD57, KIRs, and NK-G2D [573,574]. As discussed in the earlier section on NK cells, KIRs bind self–HLA-A, self–HLA-B, or self–HLA-C alleles and deliver an inhibitory signal into the cell and are expressed at high levels on most or all human NK cells. KIR expression by T cells may regulate effector function, such as cytotoxicity, by increasing the threshold for activation by antigenic peptide–MHC complexes, but human $KIR^+$ CD8 T cells seem to have equivalent function as CD8 T cells of the $KIR^-$ subset [575]. NKG2D expression may serve as a means to enhance CD8 T-cell effector function [574].

Human effector CD8 T cells also can be distinguished from circulating naïve CD8 T cells by surface phenotype. Most human CD8 effector cells have a $CD45RA^{hi}$ $CD27^-CD28^-$ surface phenotype and a high capacity to mediate cytotoxicity directly (high levels of intracellular perforin and granzyme staining) and to produce $T_H1$-type effector cytokines, including TNF-α and IFN-γ [542,572]. By contrast, naïve CD8 T cells have a $CD45RA^{hi}$ $CD27^+CD28^+$ surface phenotype and a limited ability to mediate cytotoxicity and to secrete these cytokines.

Compared with naïve T cells, memory T cells generally have a lower activation threshold, are less dependent on these costimulatory signals, and can commit to proliferate after engagement of αβ-TCR more quickly than naïve T cells [576]. This increased responsiveness of memory T cells compared with naïve T cells reflects a reprogramming of gene expression by epigenetic changes, such as DNA methylation, histone modifications, and chromatin remodeling and alterations in transcription factors [577].

The tissue localization of memory T cells is determined by differential expression of adhesion molecules and chemokine receptors. Distinct central (lymphoid homing) and effector (nonlymphoid tissue homing) memory T-cell populations in humans have been identified [571]. Central memory T cells express CCR7 receptor and high levels of L-selectin, whereas, in contrast, most effector memory T cells lack CCR7 and express low levels of L-selectin. Most effector memory T cells express adhesion molecules other than L-selectin that help target them to specific tissues. In humans, the generation of $T_H1$ and $T_H17$ $CCR7^{lo}$ (effector memory) CD4 T cells is impaired in genetic deficiency of the IL-12Rβ1 chain [553,578],

a component for signaling via the IL-12 receptor (required for $T_H1$ development) and the IL-23 receptor (which enhances $T_H17$ immunity). Central memory CD4 T cells typically show reduced antigen-specific expression of certain cytokines, such as IFN-γ, compared with the effector memory subset, whereas IL-2 production is similar or higher by the central memory subset compared with effector memory CD4 T cells [579,580].

The central memory pool may be a larger fraction of the memory pool for CD4 than for CD8 T cells. Human central memory CD4 T cells also have a lower turnover [581] and are more responsive to maintenance signals provided by cytokines, such as IL-2 and IL-7, compared with effector memory CD4 T cells [582]. Although the precursor-product relationship between central and effector memory T cells is controversial [542], there is strong evidence that central memory CD4 T cells are the precursors of effector memory cells, at least in primates. In chronic simian immunodeficiency virus infection, a progressive decline in central memory CD4 T cells ultimately results in effector memory CD4 T-cell insufficiency and increased viral-induced disease [583].

Turnover of memory CD4 and CD8 T cells seems to be much more frequent than turnover of their naïve counterparts, suggesting that the process is a dynamic one [563]. In contrast to naïve T cells, the maintenance of memory T cells seems not to require continued contact with self-peptide–MHC complexes, but does require IL-7 and IL-15 [484]. Most memory CD4 T cells require both cytokines for survival, whereas most memory CD8 T cells require IL-15, but not IL-7 for survival [484]. IL-7 also may be required to promote the transition of effector CD8 T cells to memory cells, although signaling via specific IL-7 receptors is insufficient for this conversion [584].

### Memory T-Cell Activation

When memory T cells reencounter antigenic peptide–MHC complexes ("recall antigen") as part of the secondary response, they are activated and undergo expansion and differentiation into a secondary effector population (see Fig. 4–12). The secondary immune response to recall antigen is typically more rapid and robust than the primary response to an antigen that has never been encountered previously. This difference is due to the greater frequency of antigen-specific memory T cells than of naïve T cells with TCRs that recognize the same antigenic peptides and to the enhanced function of these memory T cells and their secondary effector progeny. This increased responsiveness of memory T cells is the result of reprogramming of gene expression by epigenetic changes such as DNA methylation, histone modifications, chromatin remodeling of genes involved in effector functions such as IFN-γ genetic locus [585], and alterations in transcription factors [586,587]. In addition, there are alterations of the proximal signaling cascade that may reduce the activation threshold for memory T cells compared with naïve T cells [588]. The quality of the effector immune response may also be enhanced. Individual secondary effectors generated from memory CD8 T cells may express perforin and effector cytokines, whereas primary effectors generated from naïve CD8 T cells may express either perforin or cytokines, but not both [589].

### Postnatal Ontogeny of Memory CD4 T-Cell Subsets

The memory CD4 T-cell subset in infants and young children has a significantly higher ratio of central memory to effector memory CD4 T cells than that observed in adults [579]. The frequency of effector memory CD4 T cells that can produce IFN-γ and the amount of IFN-γ produced per cell in response to bacterial superantigen are similar in the blood of infants and young children and adults, however [579]. This finding indicates that effector memory cells generated during infancy are functionally similar to those of adults. It is likely that the greater proportion of central memory cells also applies to memory CD4 T-cell responses that occur in the first few months of life, but this remains to be shown. The mechanism responsible for the greater fraction of central memory cells in infants and children is unclear. One possibility is that the decreased proportion of effector memory CD4 T cells may reflect reduced activity of IL-12–dependent $T_H1$ pathway because effector memory CD4 T cells are markedly reduced in IL-12Rβ1 deficiency, which ablates IL-12p70 [553].

## PRODUCTION OF CYTOKINES, CHEMOKINES, AND TUMOR NECROSIS FACTOR–LIGAND PROTEINS BY NEONATAL T CELLS

### CD4 T-Cell Cytokine Production

In contrast to IL-2, the production of most other cytokines or their cognate mRNAs by unfractionated neonatal T cells or the CD4 T-cell subset seems to be reduced after short-term stimulation, including with anti-CD3 mAb, mitogen, or pharmacologic agents (e.g., the combination of calcium ionophore and phorbol ester) compared with that in adult T cells. For most cytokines (IL-3, IL-4, IL-5, IL-6, IL-10, IL-13, IFN-γ, and GM-CSF), this is a marked reduction [91,92,528,590,591]; for a few, such as TNF-α [592], the reduction is modest. As with neonatal T cells, naïve T cells from adults have a reduced capacity to produce most of these cytokines compared with adult memory/effector T cells [593–596], although adult naïve T cells may produce substantial amounts of IL-13 [597]. The low capacity of neonatal T cells to produce IFN-γ and IL-4 is due to an almost complete absence of IFN-γ and IL-4 mRNA-expressing cells [528], which is paralleled by a lack of cells expressing detectable levels of these cytokines after polyclonal activation and analysis by flow cytometry after intracellular staining [392,598,599]. Together, these results suggest that much of the apparent deficiency in cytokine production by neonatal T cells is accounted for by the fact that almost all neonatal T cells are naïve and lack antigenic experience.

Highly purified naïve CD4 T cells from neonates also have a reduced capacity to produce IFN-γ in vitro compared with adult naïve CD4 T cells after more prolonged stimulation with the same pool of moDCs from multiple unrelated blood donors [533]. This finding strongly suggests that the capacity of neonatal naïve CD4 T cells to produce IFN-γ is intrinsically more limited, even when a potent, physiologic APC population is used for antigen presentation.

In contrast to short-term stimulation, IL-10 production by anti-CD3 mAb and IL-2–stimulated neonatal CD4 T cells may be substantially higher than by adult naïve CD4 T cells after more prolonged incubation [600]. Whether these IL-10–producing neonatal CD4 T cells are derived from non-Treg versus natural Treg cell populations is uncertain, but, regardless, increased production of IL-10 by T cells in vivo would be expected to inhibit APC and effector T-cell function [601].

## CD8 T-Cell Cytokine and Chemokine Production

Cytokine production by neonatal CD8 T cells has not been as well characterized as for the CD4 T-cell subset. The lack of a memory (CD45RO$^{hi}$) CD8 T-cell subset in the neonate seems to account for reduced production of the chemokine CCL-5 (RANTES) by neonatal T cells compared with adult cells [602]. A striking result, which needs to be confirmed, is that neonatal naïve CD8 T cells produce substantially more IL-13, which is characteristic of $T_H2$ immune responses, than that produced by analogous adult cells after stimulation with anti-CD3 and anti-CD28 mAbs and exogenous IL-2 [603]. It would be of interest to determine if this unusual cytokine profile also applies to antigen-specific immune responses mediated by neonatal CD8 T cells, such as to viral pathogens.

## Postnatal Ontogeny of Cytokine Production

Neonatal T cells have been intensively studied for their cytokine secretion phenotype, but relatively little is known regarding the postnatal ontogeny of T-cell cytokine production during the first year of life. A study using phytohemagglutinin as a stimulus found that the capacity of peripheral blood lymphocytes obtained from newborns was similar to umbilical vein cord blood in having a low capacity to produce IFN-γ, IL-4, and IL-10 [604]. The capacity of peripheral blood lymphocytes to produce all three of these cytokines gradually increased during the first year of life [604], consistent with the acquisition of increased cytokine production as a result of the progressive acquisition of memory T cells resulting from exposure to foreign antigens.

## CD40 Ligand

Durandy and colleagues [605] reported that a substantial proportion of circulating fetal T cells between 19 and 31 weeks of gestation expressed CD40 ligand in vitro in response to polyclonal activation. Whether fetal T cells that can express CD40 ligand have a distinct surface phenotype from T cells lacking this capacity is unclear. By contrast, T cells from fetuses of later gestational age and from neonates have a much more limited capacity to produce CD40 ligand after activation with calcium ionophore and phorbol ester [605–608].

Expression of CD40 ligand by activated neonatal CD4 T cells remains reduced for at least 10 days postnatally, but is almost equal to adult cells by 3 to 4 weeks after birth [605] (Lewis DB, unpublished data, 2000). In most of these studies, activated neonatal CD4 T cells of cord blood expressed markedly lower amounts of CD40 ligand surface protein and mRNA than either adult CD45RA$^{hi}$ or CD45RO$^{hi}$ CD4 T cells [605–608]. Decreased CD40 ligand expression may not be due to the lack of a memory/effector population in the neonatal T-cell compartment, but may represent a true developmental limitation in cytokine production.

Decreased CD40 ligand production by neonatal T cells also has been documented in the mouse [609], suggesting that it may be a feature of RTEs. Consistent with this idea, human CD4$^{hi}$CD8$^{-}$ thymocytes, the immediate precursors of RTEs, also have a low capacity to express CD40 ligand [608,610]. Adult PTK7$^{+}$ CD4 RTEs have similar levels of CD40 ligand expression as PTK7$^{-}$ naïve CD4 T cells [433], however, indicating that the capacity for activation-induced CD40-ligand expression is upregulated before thymic emigration or shortly thereafter, at least in adults. As with most T cell–derived cytokines characteristic of effector cells [91], when neonatal T cells are strongly activated in vitro into an effector-like T-cell population, they acquire a markedly increased capacity to produce CD40 ligand on restimulation, showing that this reduction is not a fixed phenotypic feature [605,608].

In view of the importance of CD40 ligand in multiple aspects of the immune response [524,525], limitations in CD40 ligand production could contribute to decreased antigen-specific immunity mediated by $T_H1$ effector cells and B cells in the neonate. The initial studies showing a relative deficiency of CD40 ligand expression by neonatal T cells used calcium ionophore and phorbol ester for stimulation, a combination that maximizes the production of CD40 ligand, but that may not accurately mimic physiologic T-cell activation. Reduced CD40 ligand surface expression by purified neonatal naïve CD4 T cells compared with that observed in adult naïve CD4 T cells also has been observed after stimulation with various stimuli that engage the αβ-TCR–CD3 complex either alone or in combination with anti-CD28 mAb [611], suggesting that this reduction is likely to be applicable to physiologic T-cell activation. Similar results have been independently obtained for anti-CD3 and anti-CD28 mAb stimulation using unfractionated neonatal and adult T cells [612]. Others have found equivalent levels of CD40 ligand expression by neonatal and adult T cells using anti-CD3 mAb stimulation [613,614], however, suggesting that the particular in vitro conditions used (e.g., the particular anti-CD3 mAb and cell culture conditions) may influence the outcome of the assay.

The ability of neonatal and adult T cells to produce CD40 ligand in response to allogeneic stimulation, a condition that should closely mimic T-cell activation through the recognition of foreign peptide–MHC complexes, has also been studied. Neonatal CD4 T cells stimulated allogeneically can express some CD40 ligand and induce IL-12 production by DCs after 3 days of culture, but the ability of adult T cells to do so was not evaluated for comparison [615]. Another study found that CD40 ligand expression by neonatal T cells was similar to that by adult T cells after 5 days of allogeneic stimulation with irradiated adult moDCs [616]. By contrast, another study [533] found that CD40 ligand expression by

purified neonatal naïve CD4 T cells was substantially less than in adult naïve CD4 T cells after 24 to 48 hours of stimulation. This reduced CD40 ligand production was accompanied by reduced IL-12p70 production (by moDCs) and IL-2 and IFN-γ production (by naïve CD4 T cells). Together, these findings suggest that CD40 ligand surface expression initially may be more limited for neonatal naïve CD4 T cells, but that with continued priming, at least in vitro, this can be overcome with variable results [533,615,616]. The differentiation of neonatal naïve CD4 T cells into $T_H1$ effector cells by CD40 ligand–dependent and IL-12–dependent processes may be limited during the early stages of T-cell differentiation.

## Other Tumor Necrosis Factor Family Ligands

Fas-ligand, another member of the TNF ligand family, plays a key role in inducing apoptotic cell death on target cells that express Fas on the surface. Human Fas or Fas-ligand deficiency is associated with antibody-mediated autoimmunity and lymphoid hyperplasia, rather than defects in viral clearance [617]. Neonatal T cells have decreased Fas-ligand expression after anti-CD3 and anti-CD28 mAb stimulation compared with adult cells [612]. Neonatal and adult CD4 T cells express similar surface levels of Fas [541]. Iwama and colleagues [618] reported that circulating levels of Fas-ligand are elevated in newborns, but the cellular source of this protein and its functional significance are unclear. The role of Fas–Fas-ligand interactions in regulating apoptosis of neonatal T cells is discussed in the section on neonatal T-cell apoptosis.

## Mechanisms for Decreased Cytokine, Chemokine, and Tumor Necrosis Factor–Ligand Production by Neonatal T Cells

For many cytokine and TNF-ligand genes, a key event leading to de novo gene transcription is an activation-induced increase in the concentration of $[Ca^{2+}]_i$, which is required for NFAT nuclear location and transcriptional activity [619]. Certain studies comparing adult and neonatal unfractionated or CD4 T cells have suggested that neonatal T cells have substantial limitations in proximal signal transduction events that are required for the cytokine and TNF-ligand expression. These limitations include a generalized decrease in the overall level of activation-induced tyrosine phosphorylation of intracellular proteins compared with that in unfractionated adult T cells [620]; decreased activation-induced phosphorylation of CD3-ϵ; decreased phosphorylation and enzyme activity of the Lck and ZAP-70 tyrosine kinases and the ERK2, JNK, and p38 kinases [612]; reduced basal expression of protein kinase C β1, ϵ, θ, and ζ [621]; and reduced basal and activation-induced levels of phospholipase C isoenzymes [622].

It is unclear if the above-described reported deficiencies in proximal signal transduction events apply specifically to neonatal naïve T cells, but not to adult naïve T cells, because these studies used unfractionated adult T cells. In one study in which such a direct comparison was made, purified neonatal naïve CD4 T cells had a substantially reduced increase in $[Ca^{2+}]_i$ after anti-CD3 mAb cross-linkage compared with that observed in identically treated adult naïve cells [611]. Although the mechanism for this reduced calcium response remains to be defined, it is plausible that this reduction may account in part for reduced neonatal T-cell expression of genes positively regulated by NFAT, such as secreted cytokines and, as discussed later on, CD40 ligand.

Another study [623] found that the combination of activation by anti-CD3 and anti-CD26 mAb was markedly less effective for inducing proximal signaling events, such as phosphorylation of lck, and proliferation for neonatal T cells compared with adult naïve T cells. This poor activation by anti-CD26 mAb was associated with CD26 being located outside lipid raft microdomains in neonatal T cells, whereas in activated adult naïve T cells CD26 was a lipid raft component. Although the importance of CD26 in physiologic T-cell activation is uncertain, these observations are of interest because they suggest that further analysis of the composition of the lipid raft microdomains of neonatal versus adult naïve T cells may provide addition insights into limitations of neonatal T-cell activation.

Reduced IL-4 and IFN-γ mRNA expression by polyclonally activated neonatal CD4 and CD8 T cells compared with that observed in adult T cells is due primarily to reduced transcription of these cytokine genes. These differences in cytokine mRNA expression do not seem to reflect solely differences in proximal signal transduction because they have been observed not only after activation through the αβ-TCR–CD3 complex [91], but also after activation with ionomycin and PMA [528], which bypass proximal signal transduction events. IFN-γ and IL-4 are expressed mainly by memory/effector T-cell populations, rather than by the naïve T-cell populations [594]; the reduced expression of these cytokines by neonatal T cells can be accounted for by the lack of memory/effector cells in the circulating neonatal T-cell population. For many genes, including the IFN-γ gene, DNA methylation of the locus represses transcription by decreasing the ability of transcriptional activator proteins to bind to regulatory elements, such as promoters and enhancers [624]. Reduced expression of IFN-γ by neonatal T cells may also result in part from greater methylation of DNA in the IFN-γ gene locus in neonatal and adult naïve T cells than in adult memory T cells [625,626]. With a detailed understanding of epigenetic alterations of the IFN-γ gene locus during T-cell development and by naïve versus memory T cells [585], a comparison of naïve T cells from neonates and adults for these epigenetic modifications may provide new insights as to mechanisms for decreased IFN-γ expression by neonatal T cells.

In addition to decreased cytokine gene transcription, decreased cytokine mRNA stability may play a role in reduced cytokine production by neonatal T cells. Decreased IL-3 production by neonatal T cells seems to be due mainly to reduced IL-3 mRNA stability, rather than to decreased gene transcription [627]. The mechanism for this reduced mRNA stability is unclear.

Decreased mRNA stability also has been observed for other cytokines after stimulation of cord BMCs [282], but whether this also holds for purified neonatal T cells has not been addressed.

## Cytokine Production by Neonatal T Cells after Short-Term In Vitro Differentiation

The generation of effector T cells from naïve precursors in response to antigen in vivo can be mimicked by in vitro stimulation, such as by engagement of the αβ-TCR–CD3 complex in conjunction with accessory cells (non–T cells contained in peripheral BMCs) and exogenous cytokines. Neonatal T cells, if polyclonally activated under conditions that favor repeated cell division (strong activation stimuli in common with the provision of exogenous IL-2), resemble antigenically naïve adult T cells in efficiently acquiring the characteristics of effector cells. These characteristics include a CD45RA$^{lo}$CD45RO$^{hi}$ surface phenotype, an enhanced ability to be activated by anti-CD2 or anti-CD3 mAb, and an increased capacity to produce cytokines (e.g., IL-4, IFN-γ) [91,628–630].

Although neonatal CD4 T cells can be effectively primed for expression of effector cytokines by strong mitogenic stimuli and provision of cytokines, such as IL-2, as already noted, their capacity to differentiate into $T_H1$ effector cells under more physiologic conditions may be more limited. Neonatal naïve CD4 T cells stimulated with allogeneic DCs were found to have decreased frequency of IFN-$\gamma^+$ cells, based on intracellular cytokine staining, compared with that observed in adult naïve CD4 T cells in response to short-term (i.e., 24 to 48 hours' duration) stimulation by allogeneic DCs [533].

This decreased expression of IFN-γ by neonatal CD4 T cells activated under these more physiologic conditions of DC-mediated allogeneic stimulation probably is due to several factors. First, neonatal CD4 T cells are less effective than adult naïve cells at inducing the cocultured DCs to produce IL-12p70 [533], a key cytokine for promoting $T_H1$ differentiation and IFN-γ production [554]. This reduced IL-12 production is attributable, at least in part, to reduced expression of CD40 ligand by neonatal CD4 T cells in response to allogeneic stimulation using DCs [533] because engagement of CD40 on DCs by CD40 ligand is an important mechanism for inducing IL-12 production [631]. Second, CD40 ligand is also important in the acquisition of antigen-specific CD4 T cells, including cells with $T_H1$ immune function [568,569]. Third, neonatal CD4 T cells may have decreased expression of certain transcription factors, such as the NFATc2 protein [632,633], although this finding is controversial [634]; such a reduction could limit the induction of IFN-γ gene transcription and IL-2 and CD40 ligand expression in response to T-cell activation [635]. Fourth, the greater methylation of DNA of the IFN-γ genetic locus in neonatal T cells than in adult naïve T cells may also contribute to a reduced and delayed acquisition of IFN-γ production after activation in vitro [626]. Together, these mechanisms intrinsic to the T cell and immaturity of cDC function (see earlier) may account for the delayed acquisition of IFN-γ production by antigen-specific CD4 T cells after infection in the neonatal period (see later section on antigen-specific T-cell function in the fetus and neonate).

In contrast to impaired $T_H1$ generation by neonatal CD4 T cells, it has been argued that there is skewing toward $T_H2$ development in the human fetus and neonate similar to what has been observed in neonatal mice [636]. There is also considerable interest in using the production of $T_H2$ cytokines by cord BMCs or T cells as a predictor of the later development of atopic disease [637]. Purified naïve (CD45RA$^{hi}$) neonatal T cells proliferate substantially more in response to IL-4 than do analogous adult cells [638], suggesting a way by which neonatal T cells might be more prone to become $T_H2$ effectors. Studies by Delespesse and associates [491] also suggest that neonatal and adult CD45RA$^{hi}$ CD4 T cells may differ in their tendency to become $T_H2$-like effector cells under certain conditions in vitro; when these cells were primed using a combination of anti-CD3 mAb, a fibroblast cell line expressing low amounts of the CD80 costimulatory molecule, and exogenous IL-12, production of IL-4 by neonatal CD4 T cells was enhanced compared with adult cells. These investigators found that the neonatal effector T cells generated had a substantially lower capacity to produce IFN-γ than adult cells, and these differences persisted even when endogenous IL-4 was blocked with an anti–IL-4 receptor antibody [639].

Such skewing is not evident for increased production of IL-4 by neonatal CD4 T cells compared with adult naïve CD4 T cells after stimulation with allogeneic DCs [533]. Also, many studies equate IL-13 with IL-4 as an indicator of a $T_H2$ response. There is substantial evidence, however, that IL-13 and IL-4 are not invariably coexpressed, suggesting that they may have distinct roles in immune function rather than being equivalent indicators of a $T_H2$ response. IL-13, in contrast to IL-4, is produced by adult CD454RA$^{hi}$ and CD45RO$^{hi}$ CD4 T cells [597] and is expressed at high levels by neonatal CD8 T cells [603].

## Cytokine Production after Long-Term In Vitro Generation of Effector CD4 T Cells

Activated neonatal CD4 T cells can be differentiated in vitro into either $T_H1$-like or $T_H2$-like effector cells by incubation for several days to weeks with IL-12 and anti-IL-4 antibody or with IL-4 and anti-IL-12 antibody [491,640–643]. Consistent with this ability to differentiate into $T_H1$ cells, activated neonatal and adult naïve CD4 T cells upregulate expression of the IL-12Rβ1 and IL-12Rβ2 chains similarly [640,644]. In many cases, IL-2 is added after the initial activation phase to promote survival and expansion of the effector cells. Treatment of neonatal T cells with IL-4 and anti–IL-12 upregulates GATA-3 [645], the master transcription factor promoting $T_H2$ effector generation [312]. Treatment of neonatal CD4 T cells with the combination of IL-12 is effective at inducing T-bet, the master transcriptional regulator promoting $T_H1$ effector generation [642]. Mature single-positive (CD4$^{hi}$CD8$^-$ or CD4$^-$CD8$^{hi}$) fetal thymocytes obtained by 16 weeks of gestation can be also differentiated into either $T_H1$ or $T_H2$ effector cells by such

cytokine treatment [646], indicating that the capacity to acquire a polarized cytokine profile is established early in fetal life. This tendency of neonatal CD4 T cells to develop a $T_H2$-like or $T_H0$-like cytokine profile may not apply to more physiologic conditions of stimuli, however, because no IL-4 production by neonatal naïve CD4 T cells was detected in response to allogeneic DC stimulation [533].

IL-17–producing T cells, indicative of $T_H17$ generation, can be generated from neonatal cord blood CD4 T cells, but not from adult naïve CD4 T cells [647]. These IL-17–producing cells generated in vitro are similar to cells in the adult circulation in their expression of ROR$\gamma$t, a key transcription factor required for $T_H17$ generation in vivo, and their high levels of expression of the CCR6 chemokine receptor [647]. The capacity for neonatal CD4 T cells to become $T_H17$ cells is limited to a small $CD161^+$ subset that is absent from the circulating adult naïve CD4 T-cell compartment. Despite its expression of CD161 (also known as NK1.1 in mice), which is expressed on NK and NKT cells, this $CD161^+$ T-cell population is distinct from NKT cells by its diverse αβ-TCR repertoire and in being MHC class II–restricted rather than CD1d-restricted in its activation [647]. One possibility to explain these age-related differences is that the $CD161^+$ population may preferentially home after birth to sites known to be rich for the generation of $T_H17$ cells, such as gastrointestinal mucosa, and not subsequently recirculate. The capacity of neonatal CD4 T cells to differentiate in vitro into $T_{FH}$ cells has not yet been defined.

## T CELL–MEDIATED CYTOTOXICITY

T cell–mediated cytotoxicity involves two major pathways of killing of cellular targets either through the secretion of the perforin and granzyme cytotoxins or through the engagement of Fas by Fas-ligand (Fig. 4–13). The growing use of cord blood for hematopoietic cell transplantation and the finding that its use is associated with reduced graft-versus-host disease compared with that seen with adult bone marrow have led to great interest in the capacity of neonatal T cells to mediate cytotoxicity and to potentiate graft rejection.

Early studies mostly used unfractionated mononuclear cells as a source of killer cells in various non–antigen-specific assays, such as lectin-mediated cytotoxicity or redirected cytotoxicity using anti-CD3 mAb. Reduced cytotoxicity was observed with lectin-activated cord blood lymphocytes, particularly if purified T cells were used [648,649]. T cells also can be sensitized in vitro for cytotoxicity using allogeneic stimulator cells followed by testing for cytotoxic activity against allogeneic target cells. Using this approach, most studies have found that neonatal T cells are moderately less effective than adult T cells as cytotoxic effector cells [650–653]. As with the acquisition of $T_H1$ effector function by neonatal CD4 T cells, more substantial defects in T cell–mediated cytotoxicity by neonatal T cells after allogeneic priming is observed when no exogenous cytokines, such as IL-2 [654,655], are added, suggesting that this decreased cytolytic activity might be physiologically significant in vivo.

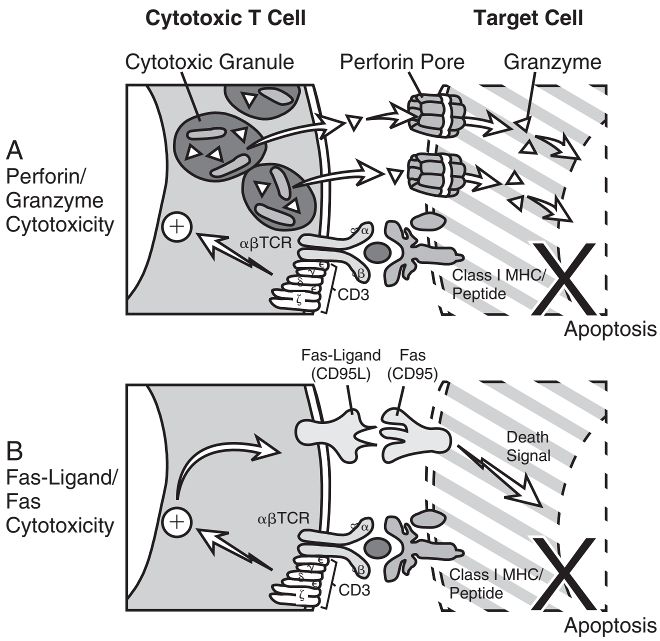

**FIGURE 4–13 Two major mechanisms of antigen-specific major histocompatibility complex (MHC) class I–restricted T cell–mediated cytotoxicity.** Engagement of αβ T-cell receptor (αβ-TCR) of $CD8^+$ T cells by antigenic peptides bound to MHC class I molecules on the target cell leads to T-cell activation and target cell death. **A,** Cytotoxicity may occur by extracellular release of the contents of cytotoxic granules from the T cell, including perforins, granzymes, and other cytotoxins, such as granulysin. Perforins introduce pores by which granzymes can enter into the target cell leading to the triggering of apoptosis and cell death. **B,** Activation of T cells results in their surface expression of Fas ligand which engages Fas on the target cell, resulting in the delivery of death signal culminating in apoptosis. Other related molecules, such as TRAIL (TNF-related apoptosis-inducing ligand), may also play a role in cytotoxicity.

The mechanism for reduced neonatal T cell–mediated cytotoxicity is poorly understood. Two studies have found that only a low percentage of neonatal CD8 T cells constitutively express perforin, whereas approximately 30% of adult CD8 T cells contain this protein [656,657]. By contrast, another study found that approximately 30% of neonatal T cells expressed perforin, a frequency that was similar to the frequency for adult T cells [658].

Effector and memory CD8 T cells kill more efficiently than antigenically naïve T cells after stimulation with lectin or anti-CD3 mAb [659] or after allogeneic sensitization [570,660]. The apparent deficiency of neonatal cytotoxic T lymphocyte (CTL) activity after in vitro activation or priming may partially reflect the absence among neonatal CD8 T cells of effector and memory cells [542].

Until more recently, the capacity of fetal T cells to mediate cytotoxicity has not received as much scrutiny, despite its relevance to the development of fetal therapy using HSCs. CD8 T cells bearing αβ-TCRs can be cloned as polyclonal lines from human fetal liver by 16 weeks of gestation [661,662]. These CD8 T-cell lines have proliferative activity in response to allogeneic stimulation, but their reactivity toward HLA antigens and their cytolytic activity are unknown. More compelling are studies documenting robust fetal effector CD8 T-cell responses, including clonal expansion and perforin expression, in

response to congenital CMV infection [663], although these responses may include limitations in IFN-γ secretion and recognition of specific viral antigens [664,665] (see "T-Cell Response to Congenital Infection"). Nevertheless, these findings show that the capacity to generate a functional CD8 T-cell effector population in vivo is established in utero, at least under conditions of chronic stimulation.

## EFFECTOR T-CELL MIGRATION

As already noted, the differential expression of chemokine receptors by T cells is important in their selective trafficking either to sites where naïve T cells may potentially encounter antigen for the first time, such as the spleen and lymph nodes, or to inflamed tissues for effector functions [98]. CCR7 expression by naïve T cells allows these cells to recirculate between the blood and uninflamed lymphoid organs, which constitutively express the two major ligands for CCR7: CCL19 and CCL21. Naïve T cells in the adult express CCR1, CCR7, and CXCR4 on their surface and have low to undetectable levels of CCR5. The role served by CCR1 and CXCR4 expression on naïve T cells is unclear, and CCR1 may be nonfunctional in this cell type [666]. Neonatal naïve T cells have a phenotype similar to those of adult naïve cells except that they lack CCR1 surface expression. Also, in contrast to adult naïve T cells, they do not increase CXCR3 expression, and they do not decrease CCR7 expression, after activation by means of anti-CD3 and anti-CD28 mAbs [488,667]. The CCR7 expressed on neonatal T cells is functional and mediates chemotaxis of these cells in response to CCL19 and CCL21 [668]. These results suggest that activated neonatal T cells may be limited in their capacity to traffic to nonlymphoid tissue sites of inflammation and, instead, may continue to recirculate between the blood and peripheral lymphoid organs.

CCR5 recognizes numerous chemokines that are produced at high levels by leukocytes at sites of inflammation, including CCL2 (MIP-1α), CCL4 (MIP-1β), and CCL5 (RANTES), and is an important chemokine receptor for the entry of T cells into inflamed or infected tissues. Neonatal T cells can increase their surface expression of CCR5 by treatment with either mitogen or IL-2 [669]. The observation that CCR5 is expressed by fetal mesenteric lymph node T cells during the second trimester of pregnancy [424] suggests that this CCR5 can be upregulated in vivo by a mechanism that does not involve antigenic stimulation. CCR5 expression on CD4 T cells gradually increases after birth, in parallel with the appearance of memory cells, suggesting that this process occurs in vivo as part of memory cell generation [670].

Neonatal naïve CD4 T cells also have the capacity after long-term in vitro differentiation to acquire expression of chemokines characteristic of $T_H1$ or $T_H2$ effectors after exposure to polarized cytokine milieu (IL-12 and anti–IL-4 for $T_H1$ and IL-4 and anti–IL-12 for $T_H2$). The $T_H1$ effectors generated in vitro tend to express CXCR3, CCR5, and CX3CR1, whereas $T_H2$ effectors tend to express CCR4 and, to a lesser extent, CCR3 [671–673]. Studies of freshly isolated memory CD4 T cells suggest that expression of CXCR3 and CCR4 may be more accurate predictors of cells with $T_H1$ and $T_H2$ cytokine profiles [548,674]. In many cases, a combination of chemokine receptors—for example, CXCR3 and CCR5 for the $T_H1$ cytokine producers—may be the most predictive of highly polarized patterns of cytokine production by memory T cells [548].

## TERMINATION OF T-CELL EFFECTOR RESPONSE

To prevent excessive immune responses, mechanisms for terminating the T-cell response operate on multiple levels. CD45 is a protein tyrosine phosphatase that promotes T-cell activation by counteracting the phosphorylation of tyrosine residues that inhibit the function of tyrosine kinases involved in T-cell activation, such as Lck. Because dimerization of CD45 impedes its phosphatase activity, it is possible that the preferential expression of the low-molecular-weight CD45RO isoform on effector CD4 T cells may facilitate CD45 dimerization and attenuate the immune response [675]. T-cell activation is also limited by the engagement of cytotoxic T lymphocyte antigen-4 (CTLA-4) (i.e., CD152) on the T cell by CD80 and CD86 on the APC. CTLA-4 is expressed mainly on the T-cell surface during the later stages of activation. How CTLA-4 acts to terminate T-cell activation is controversial and includes its competition with CD28 for costimulatory B7 family members and potential ligand-independent mechanisms [676]. The engagement of the B7 family member PD-1 on activated T cells by its B7 family ligands PDL1 (B7-H1) and PDL2, expressed on APCs (see Table 4–4) and in certain tissues, also dampens the effector T-cell response, particularly within parenchymal tissues [522,676]. As discussed next, most effector T cells generated during a robust immune response to infection are eliminated by apoptosis, which is important in preventing autoimmune pathology.

### Regulation of T-Cell Expansion by Apoptosis

The elimination of effector T cells by apoptosis is important for lymphocyte homeostasis; a failure of this process results in autoimmunity and severe immunopathology, such as hemophagocytosis [677]. Activated T cells express surface Fas molecules [678] and downregulate expression of the intracellular Bcl-2 and Bcl-xL proteins that protect against apoptosis [679]. Effector T cells may also have increased expression of other Bcl-2 family members that antagonize Bcl-2 and Bcl-xL, such as Bad and Bim, or that directly promote apoptosis downstream, such as Bax and Bcl-xS [677]. The balance between the activity of prosurvival and proapoptotic Bcl-2 family members determines whether the integrity of mitochondria is maintained to prevent the release proteins that trigger apoptosis, such as cytochrome *c*. This net apoptotic tendency is countered by signals through the IL-2 receptor complex, which maintains or increases expression of Bcl-XL, making effector T cells highly dependent on IL-2 (or other cytokines that signal through the γc cytokine receptor) for their survival [677].

Apoptosis can be studied using effector T cells that are generated in vitro from naïve precursors either by acutely

withdrawing exogenous cytokines, such as IL-2, used in effector generation, or by reactivating the effector cells (e.g., using anti-CD3 mAb). This Bcl-2-regulated pathway of apoptosis can also be induced by cytotoxic drugs, such as glucocorticoids. In addition, activated T cells upregulate their expression of Fas and other receptors, such as the p55 (type I) and p75 (type II) TNF-α receptors (TNFRs), which contain cytoplasmic death domains. The ligation of Fas by Fas-ligand on another cell results in the activation of a death receptor–regulated pathway of apoptosis, and a similar process occurs with the engagement of other surface TNFRs [677,680].

An early event in the death receptor–regulated pathway is the activation of caspase-8, a member of a group of proteases that are primarily involved in the regulation of apoptosis and that is associated with the cytoplasmic domains of death receptors. The Bcl-2-regulated and death receptor–regulated pathways of apoptosis have a final common pathway in which downstream effector caspases (caspase-3, caspase-6, and caspase-7) proteolytically cleave a group of proteins that irrevocably commit the cell to undergo apoptosis. These include activation of caspase-activated DNase, which is involved in the internucleosomal cleavage of genomic DNA into 200- to 300-bp fragments that are characteristic of apoptosis [677].

Circulating mononuclear cells from cord blood, including naïve CD4 T cells, are more prone than cells from the adult circulation to undergo spontaneous apoptosis in vitro [511,515,681,682]. The mechanism is most likely mediated by the Bcl-2-regulated pathway of apoptosis and probably does not involve Fas engagement because Fas levels are low to undetectable on freshly isolated neonatal lymphocytes, including CD4 and CD8 T cells [682–685]; high levels of Fas expression are limited mainly to memory/effector cells, which are largely absent in the neonatal circulation [684]. The increased tendency of neonatal naïve CD4 and unfractionated T cells to undergo apoptosis may be related to their expression of a lower ratio of Bcl-2 (antiapoptotic) to Bax (proapoptotic) protein compared with that in adult T cells [511,686]. Neonatal naïve T cells have a more marked decrease than adult T cells in expression of Bcl-2 and Bcl-XL (also antiapoptotic) after 7 days in culture without exogenous cytokines [515]. Treatment of neonatal naïve CD4 T cells with IL-7 can block spontaneous apoptosis [496,515,516], and this effect is accompanied by increased expression of Bcl-2 and Bcl-XL [496,515]. The tendency for neonatal T cells to undergo apoptosis spontaneously in mononuclear cell culture can also be blocked by incubation with insulin-like growth factor-I (IGF-I) [682], but the mechanism involved is unclear. The circulating levels of soluble Fas, soluble TNF, and soluble p55 TNFR increase in the first several days after birth [687], and it has been proposed that the apoptotic tendency of neonatal lymphocytes may be downregulated in the immediate postnatal period by these factors.

Although neonatal T cells have an increased tendency to undergo spontaneous apoptosis, their activation in vitro (priming) may render them less prone than adult cells to undergo apoptosis by Fas-ligand or TNF-α engagement, probably because they express less Fas, p55 TNFR, TNFR-associated death domain (TRADD) (which associates in the cytoplasm with pro–caspase 8), and effector caspases such as caspase-3 that are involved in this process [686,688]. By contrast, restimulation of primed neonatal T cells using anti-CD3 mAb induces greater apoptosis than occurs with use of similarly treated adult T cells; this anti-CD3 mAb–induced pathway in neonatal cells seems to be Fas-independent [688].

These results suggest a mechanism by which the clonal expansion of neonatal T cells might be limited after activation through the αβ-TCR–CD3 complex and the means to counteract this apoptotic tendency, such as administration of IL-2, other exogenous γc cytokine receptor–using cytokines, or IGF-I or IL-6 (which is induced by IGF-I in cultures of neonatal mononuclear cell culture) [689]. It is unclear, however, whether adult naïve T cells primed under the same conditions as for neonatal T cells retain the tendency of unfractionated adult T cells for greater Fas-mediated and p55 TNFR–mediated apoptosis and reduced anti-CD3 mAb–mediated apoptosis. A tendency for greater apoptosis after anti-CD3 activation mAb stimulation of neonatal CD4 T cells does not seem to be due to their consisting mainly of RTEs because no significant differences have been found between the frequency of apoptotic cells after CD3 and CD28 mAb stimulation of adult PTK7$^{+}$ CD4 RTEs and PTK7$^{-}$ naïve CD4 T cells (Lewis DB, unpublished observations, 2008).

Neonatal circulating mononuclear cells, probably including T cells, also are more prone than adult mononuclear cells to undergo apoptosis after engagement of MHC class I achieved by mAb treatment [681], apparently by a mechanism independent of Fas–Fas-ligand interactions. The physiologic importance of the spontaneous and MHC class I–induced apoptotic pathways for fetal lymphocytes is unclear. It is plausible that an increased tendency of fetal T lymphocytes to undergo apoptosis after engagement of MHC class I might be a mechanism to maintain tolerance against noninherited maternal alloantigens.

An important caveat of most of the above-described studies of T-cell apoptosis is that they have mainly used cord blood from term deliveries as a T-cell source. It is unclear if this proapoptotic tendency of neonatal naïve T cells applies to the fetus or early postnatal period, and, if so, if it is influenced by prematurity and circulating levels of glucocorticoids. In most studies, there also has not been a direct comparison of neonatal T cells, which are predominantly antigenically naïve, with antigenically naïve adult T cells. Non-Treg populations have not been assessed separately from neonatal Tregs, which seem to be intrinsically resistant to apoptosis (see later).

## UNIQUE PHENOTYPE AND FUNCTION OF FETAL T-CELL COMPARTMENT

As discussed in the sections on CD45 isoforms and regulatory T cells of the fetus and neonate, a substantial proportion of splenic T cells of the second-trimester fetus, but not the young infant, are CD45RA$^{lo}$CD45RO$^{hi}$ [498]. Most likely, these fetal T cells, which have a diverse αβ-TCR repertoire, are mainly Tregs because they have phenotypic features (e.g., high levels of surface CD25) and functional features (e.g., high proliferative responses to IL-2, but limited activation by anti-CD3 mAb) [498] that are suggestive of this T-cell subset [505,506].

It is unclear if the CD45RA$^{hi}$CD45RO$^{lo}$ subset of the second-trimester fetus has substantial differences from circulating or splenic T cells of the neonate in terms of function after mAb stimulation.

Mucosal T cells are present in the fetal intestine by 15 to 16 weeks of gestation, and these cells have the capacity to secrete substantial amounts of IFN-$\gamma$ after treatment with anti-CD3 mAb in combination with exogenous IFN-$\alpha$ [690]. IFN-$\alpha$ helps direct differentiation of naïve CD4 T cells, including cells of the neonate, toward a $T_H1$ effector cytokine profile dominated by production of IFN-$\gamma$, and not IL-4, IL-5, or IL-13 [640], although it does not replace a requirement for IL-12p70 in this context. A similar mechanism may occur in these fetal explant cultures. Although it is unclear what T-cell type is the major source of IFN-$\gamma$ in this tissue, these observations suggest the possibility that a similar $T_H1$ skewing of T-cell responses might occur in cases of fetal viral infection involving the intestine in which type I IFN (IFN-$\alpha/\beta$) is induced.

### Fetal Extrathymic T-Cell Differentiation

The human fetal liver contains rearranged VDJ transcripts of the TCR $\beta$ chain by 7.5 weeks of gestation, and pre-T$\alpha$ transcripts can be found at 6 weeks of gestation [661,662]. This raises the possibility that extrathymic differentiation of $\alpha\beta$-TCR–bearing T cells could occur in the fetal liver before such differentiation in the thymus. In the adult liver, CD4$^{hi}$CD8$^{-}$ and CD4$^{-}$CD8$^{-}$ T cells with characteristics distinct from those of NKT cells (which also may have, in part, an extrathymic origin) have been described in conjunction with detection of transcripts for pre-T$\alpha$ and *RAG* genes. It is possible that some liver T cells may be generated in situ even in adults.

Extrathymic differentiation of $\alpha\beta$ T cells may occur in the fetal intestine because the lamina propria of the fetal intestine contains CD3$^{-}$CD7$^{+}$ lymphocytes expressing pre-T$\alpha$ transcripts by 12 to 14 weeks of gestation, and these cells have the capacity to differentiate into $\alpha\beta$ T cells [691]. Although it is unclear if these CD3$^{-}$CD7$^{+}$ precursor cells have a thymic or other origin, the V$\beta$ repertoire of $\alpha\beta$ T-lineage cells in the fetal intestine differs substantially from that of contemporaneous fetal $\alpha\beta$ T-lineage cells found in the circulation, suggesting their independent origin [691]. Extrathymic intestinal T-cell development has been shown to occur in mice in specialized structures of the small intestine (cryptopatches), but no analogous structures containing immature lymphocytes have been observed in humans [692]. In humans, the lamina propria and epithelium of the jejunum are potential sites of extrathymic T-cell development in adults, in that immature lymphocytes with markers indicative of T-lineage commitment (CD2$^{+}$CD7$^{+}$CD3$^{-}$) are found at these sites. These cells colocalize with transcripts for pre-T$\alpha$ and *RAG-1* gene [693], consistent with this tissue being a site of T-cell differentiation.

## REGULATORY T CELLS

### Overview

Regulatory T cells (Tregs) are $\alpha\beta$ T cells that are crucial for inhibiting immune responses to autoantigens, transplantation antigens, and antigens derived from normal endogenous bacterial flora of the gut and may be important in maintenance of maternal-fetal tolerance [694–697]. Tregs are highly enriched within the small fraction of circulating human CD4 T cells that are CD25$^{hi}$, express the Foxp3 transcription factor, and lack expression of CD127 (IL-7 receptor $\alpha$ chain) [698]. CD25 is the IL-2 receptor $\alpha$ chain, which, in conjunction with the IL-2 receptor $\beta$ chain and the $\gamma$c cytokine receptor, constitutes the high-affinity IL-2 receptor. CD25$^{hi}$ CD4 Tregs depend on IL-2 and high-affinity IL-2 receptors for their generation and maintenance[699] and signaling via the STAT5b pathway [700].

In addition to CD25$^{hi}$ CD4 Tregs, other cell types with regulatory activity include certain subsets of CD8 or CD4$^{-}$CD8$^{-}$ T cells and of B cells. CD25$^{hi}$ CD4 Tregs can be generated in the thymus (referred to as natural Tregs) or from peripheral CD4 T cells (referred to as adaptive Tregs). Human natural Tregs may be generated from CD4$^{+}$CD8$^{-}$ medullary thymocytes by a process of "secondary positive selection," in which these cells interact with thymic DCs displaying high levels of self-antigen and costimulatory molecules. These DCs are proposed to display high levels of costimulatory molecules as a result of their exposure to TSLP, an IL-7-like cytokine, produced by thymic epithelial cells of Hassall corpuscle [701].

Natural Tregs predominate in the healthy fetus and neonate, require the Foxp3 transcription factor for their intrathymic development, and have a circulating surface phenotype similar to that of most non-Treg naïve CD4 T cells (i.e., CD45RA$^{hi}$CD45RO$^{lo}$Fas$^{-}$) [702]. Genetic deficiency of Foxp3 (IPEX (immunodysregulation polyendocrinopathy enteropathy X-linked) syndrome) results in an absence of circulating Tregs and early postnatal or congenital onset of a severe T cell–mediated autoimmune disease (enteritis, type 1 diabetes mellitus, and other autoimmune endocrinopathies) [703].

After in vitro activation with CD3 and CD28 mAbs, these naïve CD25$^{hi}$ CD4 Tregs have decreased expression of CD45RA and increased expression of CD45RO, Fas, and glucocorticoid-induced TNF receptor (GITR) [702]. CD25$^{hi}$ CD4 Tregs with this activated phenotype predominate in adults. Although adaptive CD25$^{hi}$ CD4 Tregs have generally been thought to be derived from naïve Tregs or conventional naïve CD4 T cells, or both, more recent studies suggest that in adults most circulating Tregs may have originate from memory CD4 T cells [704].

Treg-mediated suppression requires activation through the $\alpha\beta$-TCR (e.g., antigenic peptide–MHC), but thereafter, Treg–mediated suppression is not antigen-specific. Mechanisms of inhibition may include the production of cytokines, such as IL-10, TGF-$\beta$, or IL-35 (a novel heterodimeric cytokine consisting of the IL-12/IL-23p40 and EBI-3); expression of surface molecules, such as CTLA-4; and competition for cytokines (e.g., IL-2) on which effector T-cell responses are dependent [705]. Tregs may also "regulate" effector T-cell responses by killing other T cells or APCs or both [698].

### Fetal and Neonatal Regulatory T Cells

CD25$^{hi}$ CD4 Tregs, as assessed by their lack of CD127 expression and enrichment for Foxp3 mRNA or protein expression [533,702,706], constitute about 5% to 10% of

circulating CD4 T cells in neonates [707–709], including premature neonates [541]. Most likely, these circulating Tregs are predominantly produced intrathymically based on their naïve phenotype (i.e., $CD45RA^{hi}CD45RO^{lo}Fas^{-}$) [702], whereas most circulating adult Tregs have a phenotype indicating prior activation suggesting that they are induced rather than natural Tregs [710]. These neonatal $CD25^{hi}$ CD4 Tregs are resistant to Fas-ligand–mediated apoptosis, as would be expected because of their limited Fas expression [702].

$CD4^{+}CD8^{+}$ intrathymic precursors of $CD25^{hi}$ CD4 Tregs are identifiable in the fetal thymus by 13 to 17 weeks of gestation and display an antigenically naïve surface phenotype ($CD45RA^{hi}CD45RO^{lo}CD69^{-}Fas^{-}GITR^{-}$) [505]. After leaving the thymus, these $Foxp3^{+}$ $CD25^{hi}$ CD4 Tregs enter into the fetal lymph nodes and spleen, where they acquire a phenotype indicative of activation ($CD45RA^{lo}$ $CD45RO^{hi}CD69^{+}Fas^{+}GITR^{+}$ intracytoplasmic CTLA-$4^{+}$). Despite their strikingly different surface phenotypes, the mature intrathymic $CD25^{hi}$ CD4 Treg precursors and the Tregs found in peripheral lymphoid tissue have a similar ability to suppress the activation of autologous $CD25^{-}$ CD4 T cells in vitro [505]. A large fraction of these $CD25^{-}$ CD4 and CD8 T cells in fetal lymphoid tissue express CD69 and secrete IFN-γ in the absence of $CD25^{hi}$ CD4 Tregs, indicating that they are previously activated effector cells [506].

Taken together, the above-described results suggest that natural Tregs in the human fetus acquire the capacity for suppression in the thymus before their emigration to the periphery. After entering into the peripheral lymphoid tissues, they apparently encounter potentially autoreactive $CD25^{-}$ CD4 T cells and gain Treg activity. This implies that peripheral non-Treg T cells in the fetus have an αβ-TCR repertoire that is highly enriched for autoreactive specificities, an idea supported by studies of the murine neonatal peripheral T-cell compartment [711].

In normal human pregnancy, maternal cells are routinely detectable in the fetal lymph nodes, where they seem to be responsible for the induction of fetal Tregs that are specific for maternal alloantigens [697]. Tregs with this maternal alloantigen specificity seem to persist until at least early adulthood and are likely to have an impact on the regulation of postnatal immune responses [697]. In contrast to the fetus, $Foxp3^{+}$ $CD25^{hi}$ CD4 Tregs are rare in mesenteric lymph node tissue of healthy adults [506]. This suggests that there is a dramatic postnatal decline in Tregs of the peripheral lymphoid organs, which might reflect a reduced requirement postnatally for Treg-mediated peripheral tolerance of the naïve T cells. These findings, which suggest a high level of $CD25^{hi}$ CD4 Treg activity in the fetus, may also account for the presence at birth of autoimmune disease, such as type 1 diabetes, in some cases of genetic deficiency of Foxp3, a disorder in which natural Treg development is ablated [703].

Most studies [541,708,709], but not all [712,713], have found that cord blood $CD25^{hi}$ CD4 Tregs have a similar ability as adult peripheral Tregs to inhibit $CD25^{-}$ T-cell activation. One study also found that reduced Treg activity in the cord blood may be a risk factor for children subsequently to develop allergic disease [714].

## NATURAL KILLER T CELLS

### Overview

A small population of circulating human T cells expresses αβ-TCR and CD161 (NKR-P1A), the human orthologue of the mouse NK1.1 protein. These features and others, such as CD56 and CD57 surface expression and a developmental dependence on the cytokine IL-15, also are characteristic of NK cells, as described earlier. For this reason, these T cells frequently are referred to as NKT cells. Similar to murine T cells expressing NK1.1, human NKT cells have a restricted repertoire of αβ-TCR (TCR α chains containing the Vα24Jα18 segments in association with TCR-β chains containing Vβ11 segments) [715,716] and mainly recognize antigens presented by the nonclassic MHC molecule, CD1d, rather than by MHC class I or class II molecules. CD1d-restricted antigens that can be recognized by NKT cells include certain lipid molecules, such as α-galactosylceramide (an artificial but potent stimulator of these cells derived from the sea sponge), and less well-characterized antigens derived from several species of bacteria (e.g., *Sphingomonas*) [411].

Murine studies indicate that NKT cells may be derived from $CD4^{hi}CD8^{hi}$ double-positive thymocytes by the interaction of their αβ-TCR with CD1d [715,716]. NKT-cell development in humans and mice also depends on signaling via the SLAM family, which uses SAP for intracellular signaling. NKT cells are absent in X-linked lymphoproliferative syndrome, which is due to a genetic deficiency of SAP [717].

NKT cells have the ability to secrete high levels of IL-4 and IFN-γ and to express Fas-ligand and TRAIL on their cell surface on primary stimulation, a capacity not observed with most antigenically naïve αβ T cells [411]. This rapid ability to secrete cytokines such as IFN-γ is due to these cells constitutively expressing IFN-γ mRNA with cell activation resulting in the rapid translation of cytokine mRNA into protein that is secreted [585]. Activated NKT cells, including NKT cells of humans, may also be major sources of IL-17 and IL-21 and have certain $T_H17$-like features such as constitutive expression of RORγt and functional IL-23 receptors [718,719]. NKT cells can potentially be an early source of cytokines that are characteristically secreted by $T_H1$, $T_H2$, $T_H17$, or $T_{FH}$ cells. Some NKT cells also secrete IL-10 after activation [720], which may partly mediate their regulatory activity on other effector cell populations. NKT cells are also enriched for preformed cytoplasmic stores of perforin and granzymes [720] that allows them to carry out cell-mediated cytotoxicity rapidly, in contrast to naïve CD8 T cells, which initially lack such cytotoxic capacity and acquire it only after their differentiation into effector cells.

In adults, NKT cells that express the $V\alpha24^{+}$ αβ-TCR can be divided into $CD4^{+}(CD8^{-})$ and $CD4^{-}CD8^{-}$ cell subsets. The $CD4^{+}V\alpha24^{+}$ subset has higher levels of L-selectin (CD62L) and lower surface expression of CD11a and secretion of IFN-γ and cytotoxins (perforin and granzyme A) than the $CD4^{-}CD8^{-}V\alpha24^{+}$ subset [720,721]. This suggests that the $CD4^{+}V\alpha24$ NKT cells may preferentially recirculate in secondary lymphoid tissue and act as regulatory cells, whereas $CD4^{-}CD8^{-}V\alpha24$

NKT cells may mainly serve as effector cells at sites of extralymphoid tissue inflammation.

Although the physiologic role of NKT cells in host defense remains poorly understood, they may provide an important source of early cytokines that influence the later phases of innate immunity and the nature of the subsequent adaptive immune response [411]. The ability of NKT cells to produce large amounts of cytokines in response to IL-12 alone or other cytokines raises the possibility that antigen recognition by the invariant αβ-TCR may not play a role in this early innate response, but rather be required only for the intrathymic development of these NKT cells. NKT cells have also been implicated as negative regulators of certain T cell–mediated immunopathologic responses [715,716], such as in certain autoimmune diseases, graft-versus-host disease after hematopoietic cell transplantation, and asthma [722].

### Natural Killer T Cells of the Neonate

Only small numbers of NKT cells (<1% of circulating T cells) are present in the neonatal circulation, but these subsequently increase with aging [723]. This finding suggests that NKT cells may undergo postnatal expansion (e.g., in relation to exposure to a ubiquitous antigen presented by CD1d molecules), or that their production by the thymus or at extrathymic sites occurs mainly postnatally. Neonatal NKT cells are similar to adult NKT cells in having a memory/effector–like cell surface phenotype, including expression of CD25, the CD45RO isoform, and a low level of expression of L-selectin [724,725]. In the case of murine NKT cells, many of these activation phenotypic features are found on NKT cells during intrathymic development, indicating that these are a result of differentiation rather than prior antigenic stimulation in the periphery before birth [715,716].

The neonatal NKT-cell population can be activated and expanded in vitro using a combination of anti-CD3 and anti-CD28 mAbs and cytokines [726] or by incubation with autologous DCs pulsed with α-galactosylceramide [727]. Although neonatal NKT cells have a surface phenotype similar to that of adult NKT cells, they produce only limited amounts of IL-4 or IFN-γ on primary stimulation, indicating functional immaturity [724]. This decreased capacity may be due to mechanisms similar to those for the reduced IFN-γ mRNA production by neonatal CD4 T cells, such as decreased levels of the NFATc2 transcription factor or increased methylation of the IFN-γ genetic locus (see earlier). A limitation in the rapid translation of preformed IFN-γ mRNA is also possible, although this has not been evaluated for neonatal NKT cells.

After in vitro expansion, neonatal NKT cells produce higher levels of IL-4 and lower amounts of IFN-γ than produced by similarly treated adult NKT cells [726]. The combination of reduced effector function and a memory/effector–like cell surface phenotype by neonatal (and likely fetal) NKT cells has led to the proposal [724] that these cells may have encountered self-antigens in extralymphoid tissue and as a result have become tolerized rather than effector cells. Such a process of extralymphoid tolerization for neonatal T cells in the mouse has been described [728], but it is unclear if this occurs for human fetal T cells or NKT cells. An alternative possibility is that activated fetal NKT cells may serve as negative regulators of autoreactive CD4 and CD8 T cells. This memory/effector–like surface phenotype may also be a general characteristic of the generation of NKT cells within the thymus [715,716].

The cytokine profile of neonatal NKT cells shows greater plasticity than that of adult NKT cells. Expansion of the neonatal NKT-cell population and priming using either cDCs or pDCs in conjunction with phytohemagglutinin, IL-2, and IL-7 result in an IL-4–predominant or an IFN-γ–predominant cytokine expression profile. By contrast, similarly treated adult NKT cells retain their ability to produce both cytokines [726], suggesting that these cells have lost the ability to adopt a polarized $T_H1$ or $T_H2$ phenotype after birth.

The capacity of neonatal and infant NKT cells to mediate cytotoxicity directly has not been reported. Neonatal CD56$^+$ T cells constitutively express less perforin than adult cells [657]. Because the CD56$^+$ T-cell population is highly enriched in CD1d-restricted NKT cells, NKT-cell cytotoxicity probably is limited at birth and gradually increases with age. Culturing of neonatal NKT cells in vitro for several weeks results in acquisition of potent cytotoxic activity [727,729], indicating that developmental limitations can be overcome after expansion and differentiation.

## γδ T CELLS

### Phenotype and Function

γδ T cells, which express a TCR heterodimer consisting of a γ and a δ chain in association with the CD3 complex proteins, are rarer than αβ T cells in most tissues, including the blood where they constitute approximately 1% to 10% of circulating T cells in adults. A major exception is the intestinal epithelium, where they predominate. Although some γδ-TCRs can recognize conventional peptide antigens presented by MHC, most directly recognize three-dimensional nonprotein or protein structures. The antigen-combining site of the γδ-TCR shares some structural features with that of immunoglobulin molecules [730], which is consistent with preferential recognition of three-dimensional structures by both of these receptors.

Human γδ T cells expressing the Vγ9Vδ2 (using an older but still commonly employed nomenclature for Vγ segments) can proliferate and secrete cytokines, cytotoxins (perforins, granzymes, granulysin), and growth factors after recognition of phosphoantigens (i.e., nonpeptidic pyrophosphomonoester compounds). These phosphoantigens can be derived from mycobacteria and other bacterial species or from cellular isopentenyl phosphates that are involved in cholesterol biosynthesis from mevalonate [731]. The cellular levels of isopentenyl phosphates can be increased by metabolic stress from intracellular infection, after treatment with certain drugs (e.g., aminobisphosphonates), or after oncogenic transformation [731]. The precise mechanism by which the Vγ9Vδ2 TCR recognizes exogenous or endogenous phosphoantigens is unclear, but does not involve MHC class I or class II or CD1 recognition and may instead require ATP synthase, a mitochondrial enzyme that can translocate to the cell surface [732]. Many Vγ9Vδ2 T cells express NKG2D,

which recognizes the MHC class I–like molecule MICA [733], and enhances antigen-dependent effector function [408]. Such enhancement in vivo may be a consequence of the induction of MICA on APCs by mycobacteria and other pathogens [408].

This in vitro activation of γδ T cells probably is relevant in vivo because increased numbers are found in the skin lesions of patients with leprosy and in the blood of patients with malaria and acute and chronic herpesvirus infections. Resident γδ T cells of the murine skin produce keratinocyte growth factors and IGF-I that help maintain epithelial integrity during stress [734]. The observation that MICA or MICB is expressed in the skin of patients with acute graft-versus-host disease is consistent with a similar role for human γδ T cells [735].

γδ T cells also may have important immunosurveillance function for malignancy because murine cutaneous γδ T cells can kill skin carcinoma cells by a mechanism that involves engagement of NKG2D by Rae-1 and H60 [736], which have homology with human MICA. Many human epithelial cell tumors express NKG2D ligands and can be lysed by human γδ T cells in vitro [737], which indicates that γδ T cells have a potential role in tumor immunotherapy. Murine studies also suggest that distinct subpopulations of γδ T cells appearing at sites of infection either decrease inflammatory responses to pathogens, such as *Listeria*, by killing activated macrophages by Fas-ligand–mediated cytotoxicity or contribute to macrophage activation [738].

Most activated γδ T cells express high levels of perforin, serine esterases, Fas-ligand, and granulysin and are capable of cytotoxicity against tumor cells and other cell targets, such as infected cells [739]. γδ T cells also can secrete various cytokines in vitro, including TNF-α, IFN-γ, IL-4, and IL-17 [731,740], and chemokines that may help recruit inflammatory cells to the tissues. Cytokine production can be potently activated by products from live bacteria, such as isobutylamine [741], and by type I IFN or by agents that potently induce it, such as oligonucleotides containing unmethylated CpG motifs [742]. Human Vγ2Vδ2 γδ T cells after adoptive transfer into SCID mice can mediate rapid and potent antibacterial activity against gram-positive and gram-negative bacteria, with protection associated with the production of IFN-γ [741].

Only about 2% to 5% of T-lineage cells of the thymus and peripheral blood express γδ-TCR in most individuals [743]. In contrast to in most αβ T cells, whose development requires an intact thymus, a significant proportion of γδ T cells can develop by a thymic-independent pathway, and normal numbers of γδ T cells are found in cases of complete thymic aplasia [743] and in the human fetus before the first waves of thymically derived T cells [744]. This may be explained, at least in part, by the differentiation of γδ T cells directly from primitive lymphohematopoietic precursor cells found in the small intestine, as has been shown in the mouse [745].

## Ontogeny of γδ T-Cell Receptor Gene Rearrangements

The human TCR γ and δ chain genes undergo a programmed rearrangement of dispersed segments analogous to that of the TCR β and TCR α chain genes. Most circulating adult human γδ T cells lack evidence of TCR-β chain gene rearrangement [746], indicating that commitment to this lineage mainly is the result of a double-negative thymocyte expressing a productive TCR-γ and TCR-δ chain gene rearrangement. This expression results in strong cell signaling that suppresses TCR β chain rearrangement [747]. Alternatively, if the TCR β chain gene is productively rearranged (not the TCR-γ and TCR-δ genes), signals from the pre-TCR complex and Notch signaling favor progression to the $CD4^{+}CD8^{+}$ stage where positive selection can occur [748]. Most γδ T cells lack surface expression of either CD4 or CD8α/CD8β heterodimers, consistent with their not undergoing a process of positive selection that is obligatory for αβ T cells. Whether human γδ T cells undergo negative selection is unclear.

Rearranged TCR δ genes are first expressed extrathymically in the liver and primitive gut between 6 and 9 weeks of gestation [749,750]. Rearrangement of the human TCR γ and TCR δ genes in the fetal thymus begins shortly after its colonization with lymphoid cells, with TCR δ protein detectable by 9.5 weeks of gestation [751]. γδ T cells constitute about 10% of the circulating T-cell compartment at 16 weeks, a percentage that gradually declines to less than 3% by term [497,752].

Although there is potential for the formation of a highly diverse γδ-TCR repertoire, peripheral γδ T cells use only a few V segments, which vary with age and with tissue location. These can be divided into two major groups, Vγ9Vδ2 cells and Vδ1 cells, in which a Vδ1-bearing TCR δ chain predominantly pairs with a TCR γ chain using a Vγ segment other than Vγ9. Most $\gamma\delta\text{-TCR}^{+}$ thymocytes in the first trimester express Vδ2 segments. This is followed by $\gamma\delta\text{-TCR}^{+}$ thymocytes that express Vδ1, which predominate at least through infancy in the thymus. Most circulating fetal and neonatal γδ T cells also are Vδ1-bearing, with only about 10% bearing Vδ2 [723], and these Vδ1 cells constitute the predominant γδ T-cell population of the small intestinal epithelium after birth. In contrast to the early gestation fetal thymus and the fetal and neonatal circulation, Vδ2 T cells predominate in the fetal liver and spleen early during the second trimester [590,753] and appear before $\alpha\beta\ \text{TCR}^{+}$ thymocytes [751,754], suggesting that they are produced extrathymically by the fetal liver.

As indicated by TCR spectratyping, the TCR δ chains using either Vδ1 or Vδ2 segments usually are oligoclonal at birth [755,756]. Because this oligoclonality also is characteristic of the adult γδ T-cell repertoire, this is not due to postnatal clonal expansion, but reflects an intrinsic feature of this cell lineage. By age 6 months, γδ T cells bearing Vγ9 Vδ2 segments become predominant and remain so during adulthood [757], probably because of their preferential expansion in response to ubiquitous antigens, such as endogenous bacterial flora.

## Ontogeny of γδ T-Cell Function

Antigenically naïve and experienced subsets of γδ T cells can be distinguished using markers commonly applied to αβ T cells; naïve γδ T cells can be identified by their $CD45RA^{hi}CD45RO^{lo}CD27^{hi}CD1a^{lo}$ surface phenotype [758]. By these criteria, circulating γδ T cells of the neonate are predominantly antigenically naïve [758].

Although neonatal γδ T cells proliferate in vitro in response to mycobacterial lipid antigens [759], they express lower levels of serine esterases than adult γδ T cells, suggesting they are less effective cytotoxic cells [760]. γδ T-cell clones derived from cord blood also have a markedly reduced capacity to mediate cytotoxicity against tumor cell extracts [752]. Because these neonatal clones also have lower CD45RO surface expression than observed in the adult clones, their reduced activity may reflect their antigenic naïveté. In contrast to freshly isolated neonatal αβ T cells, activation and propagation of these fetal and neonatal γδ T cells in culture (e.g., with exogenous IL-2) do not enhance their function. The function of fetal liver γδ T cells is unclear, although one report suggests that they have cytotoxic reactivity against maternal MHC class I [754] and may prevent engraftment of maternal T cells.

## ANTIGEN-SPECIFIC T-CELL FUNCTION IN THE FETUS AND NEONATE

### Delayed Cutaneous Hypersensitivity, Graft Rejection, and Graft-versus-Host Disease

Skin test reactivity to cell-free antigens assesses a form of DTH reaction that requires the function of antigen-specific CD4 T cells. Skin test reactivity to common antigens such as *Candida*, streptokinase-streptodornase, and tetanus toxoid usually is not detectable in neonates [761–763]. Absence of such reactivity reflects a lack of antigen-specific sensitization because in vitro T-cell reactivity to these antigens also is absent. When leukocytes, and presumably antigen-specific CD4 T cells, from sensitized adults are adoptively transferred to neonates, children, or adults, only neonates fail to respond to antigen-specific skin tests [764]. This finding indicates that the neonate may be deficient in other components of the immune system required for DTH reaction, such as APCs and production of inflammatory chemokines or cytokines. Such deficiencies may account, at least in part, for diminished skin reactivity in the neonate after specific sensitization or after intradermal injection with T-cell mitogens [175,765]. Diminished skin reactivity to intradermally administered antigens persists postnatally up to 1 year of age [765].

Neonates, including premature neonates, are capable of rejecting foreign tissues, such as skin grafts, although rejection may be delayed compared with adults [766]. Experiments using human–SCID mouse chimeras also suggest that second-trimester human fetal T cells are capable of becoming cytotoxic effector T cells in response to foreign antigens and in rejecting solid tissue allografts [767]. Clinical transplantation of fetal blood from one unaffected fraternal twin to another did not result in marrow engraftment, despite a sharing of similar MHC haplotypes; instead, there was a postnatal recipient cytotoxic T-cell response against donor leukocytes [768]. A T-cell response to alloantigens can also be detected in newborns after in utero irradiated red blood cell transfusions from unrelated donors [769,770]. Fetal T cells seem similar to neonatal T cells in being able to mediate allogeneic responses in vivo, including graft rejection.

Another indication that neonatal T cells can mediate allogeneic responses is the fact that blood transfusions rarely induce graft-versus-host disease in the neonate. Rare cases of persistence of donor lymphocytes and of graft-versus-host disease have developed after intrauterine transfusion in the last trimester and in transfused premature neonates, however [771–774]. Because the infusion of fresh leukocytes induces partial tolerance to skin grafts [766], tolerance for transfused lymphocytes might occur by a similar mechanism, predisposing the fetus or neonate to graft-versus-host disease. Together, these observations suggest a partial immaturity in T-cell and inflammatory mechanisms required for DTH reaction and for graft rejection.

### T-Cell Reactivity to Environmental Antigens

Specific antigen reactivity theoretically can develop in the fetus by exposure to antigens transferred from the mother, by transfer of antigen-specific cellular maternal lymphocytes, or by infection of the fetus itself. Several studies suggest that fetal T cells have become primed to environmental or dietary protein allergens as a result of maternal exposure and transfer to the fetus [775–778]. A criticism of these studies is that the antigen-specific proliferation is low compared with the basal proliferation of cord BMCs. In addition, many of these studies used antigen extracts rather than defined recombinant proteins or peptides, and these may have nonspecific stimulatory effects.

Prenatal sensitization has been assessed by antigen-induced incorporation of $^3$H-thymidine and cytokine and cytokine mRNA production by cord BMCs [778–781]. In some studies, the production of IL-10 in these cultures is high relative to that of the classic $T_H2$ cytokines (IL-4, IL-5, IL-9, and IL-13). IFN-γ production was 100-fold higher than IL-4 production, a ratio that is nonetheless still reduced compared with adult cells. This cytokine profile has been interpreted as a $T_H2$-biased response or a regulatory T-cell (IL-10–dominant) response. Its frequent occurrence suggests that $T_H2$ priming per se may be a normal outcome of fetal exposure to such antigens [778,779]. Consistent with this idea, a follow-up study found no significant relationship between $T_H2$ priming of fetal T cells to environmental antigens and the risk of developing atopic disease by 6 years of age [782].

Prenatal priming of T cells by environmental allergens can be shown by 20 weeks of gestation, based on their proliferative responses to seasonal allergens [783]. These responses are weak, however, and the cytokine profile was not reported. In one study, protein allergen–specific T-cell proliferation detected at birth was more common when allergen exposure occurred in the first or second trimester rather than in the third trimester [777]. This finding could reflect decreased maternal-fetal transport of antigen during late pregnancy or an intrinsic capacity of early and late gestation fetal T cells to be primed.

### Fetal T-Cell Sensitization to Maternally Administered Vaccines and Maternally Derived Antigens

In contrast to protein allergens, there is only one report in which antigen-specific fetal T-cell priming to influenza vaccination has been detected using a flow cytometric

assay after staining of T cells with fluorochrome-labeled influenza hemagglutinin peptide/HLA-DR (MHC class II) tetramers influenza [784]. This study, which needs to be confirmed, contrasts with one in which maternal vaccination during the last trimester of pregnancy with tetanus toxoid or inactivated influenza virus A or B did not result in detectable neonatal T-cell responses using lymphocyte blastogenesis assays [785].

The use of corroborating assays that are reliable for the detection of very low frequencies of T cells, such as enzyme-linked immunospot (ELISPOT) assays, might allow a better definition of the extent of fetal T-cell sensitization by maternal vaccination. In any case, the neonatal CD4 T-cell responses induced by maternal immunization are of a much lower frequency that postnatal vaccination responses in children [786], and their durability is unknown. Together, these findings suggest that fetal sensitization to foreign proteins may be relatively inefficient, particularly when exposure is temporally limited. Whether this reflects relatively inefficient maternal-fetal transfer of protein antigens or intrinsic limitations of the fetus for antigen presentation and T-cell priming, or both, is unclear. Even if it is assumed that the capacity for fetal T cells to be primed by foreign antigens is similar to that of antigenically naïve adult T cells, the immune response to maternally derived foreign vaccine proteins by fetal T cells would be expected to be poor compared with the maternal response because antigen probably enters into the fetal circulation with little, if any, accompanying activation of the innate response required for efficient T-cell activation.

Growing evidence suggests that fetal T-cell sensitization can occur in cases of antigen exposure owing to chronic infection of the mother with parasites or viruses. Parasite (schistosomal, filarial, and plasmodial) antigen-specific cytokine production by peripheral blood lymphocytes, probably of T-cell origin, was detectable at birth in infants without congenital infection who were born to infected mothers [787,788]. This apparent T-cell immunity persisted for at least 1 year after birth in the absence of postnatal infection with parasites and was associated with downregulation of *Mycobacterium bovis* BCG-specific IFN-γ production after neonatal administration of BCG vaccine [787]. These results suggest that fetal exposure to parasitic antigens without infection can downregulate subsequent postnatal $T_H1$ responses to unrelated antigens. HIV peptide–specific IL-2 production by cord blood CD4 T cells also has been reported in uninfected infants born to HIV-infected mothers, suggesting that fetal T-cell sensitization can occur in cases of chronic viral infection of the mother without congenital infection [789].

### Maternal Transfer of T-Cell Immunity to the Fetus

The older literature contains many reports of cord blood lymphocyte proliferation or cytokine production in response to antigens that the fetus is presumed not to have encountered. These antigen responses (e.g., for PPD, *Mycobacterium leprae*, measles, or rubella) have been attributed to passive transfer of T-cell immunity from the mother. The responses usually are weak and may represent laboratory artifacts, rather than true sensitization, because complex antigen mixtures were used that likely may activate T cells in a non-MHC–restricted manner. Although maternal-to-fetal transfer of leukocytes, particularly T cells, occurs, their number in the fetus is very low (usually <0.1%) [790], unless the neonate or infant has a severe defect of T cells that normally prevents maternal T-cell engraftment, such as SCID [791]. Detectable antigen-specific cellular immunity by conventional assays is unlikely for immunocompetent neonates. Reports of T-cell responses in healthy neonates as a result of transfer of maternal immunity should remain suspect, unless the T-cell population is identified and its antigen specificity and MHC restriction are shown.

## T-CELL RESPONSE TO CONGENITAL INFECTION

### CD4 T Cells

Pathogen-specific T-cell proliferative responses and cytokine responses (IL-2 and IFN-γ) in infants and children with congenital infection (e.g., with *Treponema pallidum*, CMV, VZV, or *T. gondii*) are markedly decreased compared with such responses in infants and children with postnatal infection or are absent entirely [792–797]. These assays mainly detected CD4 T-cell responses because antigen preparations (e.g., whole cell lysates of virally infected cells) and APC populations (e.g., peripheral blood monocytes and B cells as the predominant APCs with few cDCs) were used that favor activation of MHC class II–restricted rather than MHC class I–restricted responses. These reduced CD4 T-cell responses are particularly true with first-trimester or second-trimester infections. With severe infections in the first trimester, a direct deleterious effect on T-cell development is possible. T cells from infants and children with congenital toxoplasmosis retain the ability, however, to respond to alloantigen, mitogen, and, in one case, tetanus toxoid [797].

The adaptive immune responses to *Plasmodium falciparum* antigens have been evaluated using cord blood from neonates in an area with a high rate of fetal exposure to maternally derived malaria antigens. Malaria antigen–induced CD4 T-cell cytokine production (IFN-γ, IL-4, and IL-13) was detectable in these neonates [788,798], but not in samples from neonates in North America [788]. The limited ability of the fetus to mount CD4 T-cell responses to pathogen-derived antigens is not absolute, and dual $T_H1$-type and $T_H2$-type immune responses can develop after some congenital infections or fetal exposure to pathogenic antigens from the mother.

The reduced CD4 T-cell responses seen in many types of congenital infection may be the result of antigen-specific unresponsiveness (e.g., anergy, deletion, or ignorance—the failure of the CD4 T cell to be initially activated by antigen). As discussed earlier, it is unlikely that a decreased TCR repertoire limits these immune responses, particularly after the second trimester onward. Decreased responses do not occur to all pathogens; in one study, 10-year-old children congenitally infected with mumps had DTH reactions to mumps antigen, indicating persistence of mumps-specific memory/effector T cells [799].

## CD8 T Cells

CD8 T-cell responses to congenital infections seem to be relatively robust, which is in marked contrast to responses of CD4 T cells. In congenital CMV infection, high frequencies of CMV-specific CD8 T cells were detectable by staining with CMV peptide–MHC class I tetramers, and these cells showed perforin expression, cytolytic activity, and oligoclonal αβ-TCR expansion IFN-γ, similar to cells of chronically infected adults [663]. More recent studies found that although the CMV-infected fetus and the transmitter mother had similar levels of activated, effector/memory, and memory CMV-specific CD8 T cells, there was impaired secretion by fetal CD8 T cells of IFN-γ in response to CMV antigen or CD3 and CD28 mAb stimulation [664,665], and this impairment was associated with decreased viral clearance. Similarly, in HIV-1 infection, an expansion of HIV-specific cytotoxic T cells was detected at birth, indicating that fetal T cells were activated by viral antigens [800]. In another case of in utero HIV infection, HIV-specific T cell–mediated cytotoxicity was detected at age 4 months and persisted for several years despite a high HIV viral load [801].

Congenital infection with *Trypanosoma cruzi* also results in a marked expansion of CD8 T cells over CD4 T cells, with evidence of oligoclonality of the TCR repertoire, indicating that this is antigen-driven [802]. These CD8 T cells are enriched in markers for activation (HLA-$DR^{hi}$), memory ($CD45RO^{hi}$), and end-stage effector ($CD28^{-}$) cells and for cytotoxicity ($perforin^{+}$) and have markedly greater capacity to produce IFN-γ and TNF-α than is seen in CD8 T cells from uninfected newborns; compared with CD8 T cells, CD4 T cells in these congenitally infected newborns seem to have undergone much less clonal expansion and acquisition of effector function [802]. Congenital infection with viruses or *T. gondii* during the second and third trimesters may result in the appearance of $CD45RO^{hi}$ memory T cells and an inverse ratio of CD4 to CD8 T cells [803–805], findings that also suggest that fetal $CD8^{+}$ T cells are activated and expanded in response to serious infection. These alterations in CD45RO expression by T cells in congenital infection may persist at least through early infancy [806,807].

# T-CELL RESPONSE TO POSTNATAL INFECTIONS AND VACCINATION IN EARLY INFANCY

## CD4 T Cells

Postnatal infection with HSV results in antigen-specific proliferation and cytokine (IL-2 and IFN-γ) production by CD4 T cells. These responses are substantially delayed, however, compared with responses in adults with primary HSV infection [808,809]. It is unclear at what postnatal age the kinetics of this response becomes similar to that in adults. Studies of CMV-specific CD4 T-cell immunity (expression of IL-2, IFN-γ, and CD40 ligand) in older infants and young children with primary infection found substantially reduced responses compared with adults with infection of similar duration [579]. This reduced CD4 T-cell response was associated with persistent shedding of the virus into secretions [579]. It is likely that reduced CMV-specific CD4 T-cell responses also apply to the neonate and young infant with perinatal or postnatally acquired infection, who also persistently shed the virus for several years after acquisition. As in congenital CMV infection [663–665], older infants and young children with primary CMV infection had robust CMV-specific CD8 T-cell responses similar to those in adults [579,810,811].

Infants 6 to 12 months old also show reduced IL-2 production in response to tetanus toxoid than observed in older children and adults [812]. This finding suggests that antigen-specific memory CD4 T-cell generation or function is decreased during early infancy. It is unclear whether this reflects limitations in antigen processing, T-cell activation and costimulation, or proliferation and differentiation.

In contrast to postnatally acquired herpesvirus infections or inactivated vaccine antigens, BCG vaccination at birth versus 2 months or 4 months of age was equally effective in inducing CD4 T-cell proliferative and IFN-γ responses to PPD, extracellular *Mycobacterium tuberculosis* antigens, and *M. tuberculosis* intracellular extract [813,814]. The responses were robust not only at 2 months after immunization, but also at 1 year of age, and no skewing toward $T_H2$ cytokine production was noted, even by PPD-specific CD4 T-cell clones [813,814]. Early postnatal administration of BCG vaccine does not result in decreased vaccine-specific $T_H1$ responses, tolerance, or $T_H2$ skewing. How these responses compare with responses in older children and adult vaccinees is unknown. Early BCG vaccination also may influence antigen-specific responses to unrelated vaccine antigens. BCG given at birth increased $T_H1$-specific and $T_H2$-specific responses and antibody titers to hepatitis B surface antigen (HBsAg) given simultaneously [814]. BCG given at birth did not enhance the $T_H1$ response to tetanus toxoid given at 2 months of age, but did increase the $T_H2$ response (IL-13 production). It is likely that BCG vaccination may accelerate DC maturation, so that these cells can augment either $T_H1$ or $T_H2$ responses.

The T cell–specific response to oral poliovirus vaccine (OPV), another live vaccine, suggests a decreased $T_H1$ response. Infants given OPV at birth and at 1, 2, and 3 months of age show lower OPV-specific CD4 T-cell proliferation and IFN-γ production and have fewer IFN-γ–positive cells compared with adults who were immunized as children but not recently reimmunized [815]. By contrast, their antibody titers were higher than titers in adults, suggesting that CD4 T-cell help for B cells is not impaired. It is plausible that OPV may be less effective at inducing a $T_H1$ response than BCG in neonates and young infants because of its limited replication, site of inoculation, or ability to stimulate APCs in a manner conducive to $T_H1$ immunity, relative to BCG, which induces persistent infection in the recipient.

Although neonates and young infants have been suggested to have skewing of CD4 T-cell responses toward a $T_H2$ cytokine profile, this may be an oversimplification. The tetanus toxoid–specific response after vaccination indicates that $T_H1$ (IFN-γ) and $T_H2$ (IL-5 and IL-13) memory responses occur, particularly after the third vaccine dose at 6 months of age [547]. The tetanus toxoid–specific $T_H1$

response may transiently decrease by 12 months of age; $T_H2$ responses are not affected [547,816].

### CD8 T cells

CD8 T-cell responses to CMV infection acquired in utero [663] or during infancy and early childhood [579,800,810] are robust, and it is likely that this also applies for infection acquired perinatally or during early infancy. Cytotoxic responses to HIV in perinatally infected infants suggest that CD8 T cells capable of mediating cytotoxicity have undergone clonal expansion in vivo by 4 months of age [817]. The cytotoxicity may be reduced and delayed in appearance compared with adults, however [818]. There is also decreased HIV-specific CD8 T-cell production of IFN-γ by young infants after perinatal HIV infection [819] and an inability to generate HIV-specific cytotoxic T cells after highly active antiretroviral therapy [820]. When evaluated beyond infancy, cytolytic activity directed to HIV envelope proteins was commonly detected, but cytolytic activity directed against gag or pol proteins was rarely detected [800], suggesting that the antigenic repertoire of cytotoxic CD8 T cells was less diverse than in adults.

HIV-1 infection may inhibit antigen-specific immunity by depleting circulating DCs, impairing antigen presentation, decreasing thymic T-cell output, and promoting T-cell apoptosis. In addition, maintenance of HIV-specific CD8 T cells with effector function depends on HIV-specific CD4 T cells and may be selectively and severely impaired by the virus. Regardless of the precise mechanism, the suppressive effects of HIV-1 on cytotoxic responses may be relatively specific for HIV-1 because HIV-infected infants who lack HIV-specific cytotoxic T cells may maintain cytolytic T cells against EBV and CMV [819,820]. Some of the inhibitory effects of HIV-1 infection also may occur in HIV-exposed but uninfected infants born to HIV-infected mothers [821,822].

In one older study, RSV-specific cytotoxicity was more pronounced and frequent in infants 6 to 24 months of age than in younger infants [823]. These results, which need to be repeated using more current assays, suggest that the CD8 T-cell response to RSV gradually increases with postnatal age. Murine studies indicate that RSV infection suppresses CD8 T cell–mediated effector activity (IFN-γ production and cytolytic activity) and that only transient memory CD8 T-cell responses occur after infection. Longitudinal studies of CD8 T-cell immunity to RSV in children and adults after primary and secondary infection would be of interest to determine if this immunoevasive mechanism applies to humans.

## SUMMARY

T-cell function in the fetus and neonate is impaired compared with adults. Diminished functions include T-cell participation in cutaneous DTH reaction and, as also discussed in the next section, T-cell help for B-cell differentiation. Selectively decreased cytokine production by fetal and neonatal T cells, such as decreased IFN-γ secretion and expression of CD40 ligand, may contribute to these deficits. In the case of IFN-γ, the predominance in the fetus and neonate of RTEs may contribute to this immaturity in cytokine secretion. The repertoire of αβ-TCR probably is adequate except in early gestation. After fetal or neonatal infection, the acquisition of CD4 T-cell antigen-specific responses typically is delayed. In vitro studies suggest that deficiencies of DC function and activation and differentiation of antigenically naïve CD4 T cells into memory/effector T cells may be contributory. In contrast with diminished CD4 T-cell function, CD8 T cell–mediated cytotoxicity and cytokine production in response to strong chronic stimuli, such as congenital CMV infection or allogeneic cells, seem to be intact in the fetus and neonate. The mother does not transfer T cell–specific immunity to the fetus. T-cell sensitization to environmental allergens may occur during fetal life and with maternal vaccination, but such sensitization must be confirmed in future studies.

# B CELLS AND IMMUNOGLOBULIN

## OVERVIEW

Mature B cells are lymphocytes that are identifiable by their surface expression of immunoglobulin. Immunoglobulin, which is synonymous with antibody, is a heterotetrameric protein consisting of two identical heavy chains and two identical light chains linked by disulfide bonds (Fig. 4–14). As with the TCR, the amino-terminal

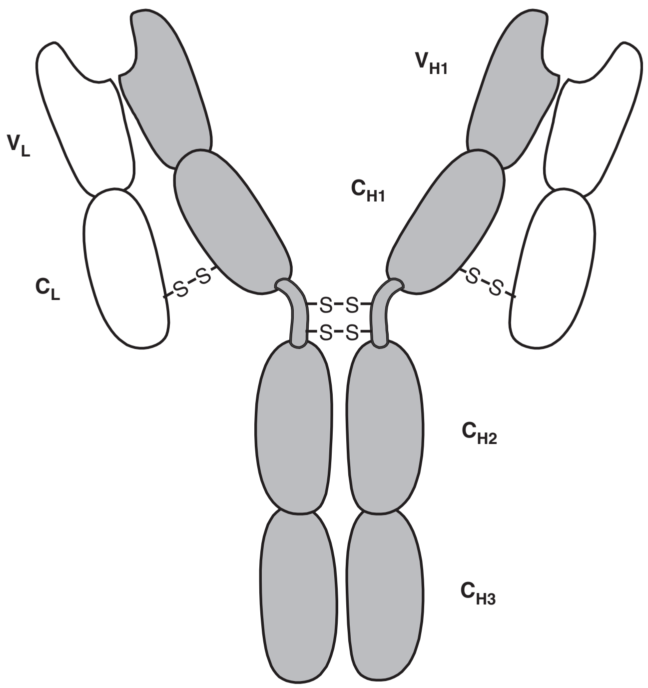

**FIGURE 4–14 Structure of immunoglobulin molecule.** An immunoglobulin molecule consists of two heavy chains (*dark shading*) and two light chains (*unshaded*) linked together by disulfide bonds. The antigen-combining site is formed by amino-terminal region of the heavy and light chains contained in the $V_H$ and $V_L$ domains of the heavy and light chains. For IgG, IgD, and IgA, the constant region $C_{H3}$ domain of the heavy chain encodes isotype or subclass specificity, which determines the ability of the immunoglobulin to fix complement, bind to Fc receptors, and be actively transported from the mother to the fetus during gestation. IgM and IgE (*not shown*) are structurally similar except that they contain an additional $C_{H4}$ domain conferring these properties, and they lack a hinge region.

portion of the antibody chains is highly variable as a consequence of the assembly of V, D, and J gene segments (heavy chain) or V and J segments (light chain) to a monomorphic constant (C) region. These amino-terminal regions of a pair of heavy and light chains form the antigen-binding fragment (Fab) portion of immunoglobulin, which contains the antigen-binding site (see Fig. 4–14).

As with the TCR, the variable region of each chain can be subdivided into three hypervariable CDR1, CDR2, and CDR3 regions and four intervening, less variable framework regions. The three-dimensional folding of the antibody molecules results in the approximation of the three CDR regions into a contiguous antigen recognition site, with CDR3 located at the center and the CDR1 and CDR2 regions forming the outer border of the site [824,825]. Antibody molecules are distinct from the αβ-TCR, however, in that they typically recognize antigens found on intact proteins or other molecules, such as complex carbohydrates. The B-cell recognition of antigen is typically highly sensitive to its three-dimensional structure.

The constant regions of the heavy and light chains consist of three constant heavy (CH) domains and one constant light (CL) domain (see Fig. 4–14). The heavy chains also have a hinge region at which the two halves are joined by disulfide bonds. The heavy chain C region is the Fc portion of immunoglobulin and contains sites that determine complement fixation, placental transport, and binding to leukocyte Fc receptors. The portion of the heavy chain C region encoded by the last exon of heavy chain gene defines antibody isotype or isotype subclass, of which there are nine in humans: IgM, IgD, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, and IgE. Light chains comprise two types, κ and λ, each containing a distinct type of C region. In isotype switching, the C region at the carboxy terminus of the immunoglobulin heavy chain gene is replaced with another isotype-specific segment, but the antigen-combining site at the amino terminus is preserved.

In addition to their secretion of antibodies, mature B cells express MHC class II and may participate in antigen processing and presentation to CD4 T cells. They may also serve as a source of effector cytokines (e.g., IFN-γ) and as suppressors of immune responses (regulatory B cells).

In cases in which the antigen has multiple and identical surface determinants (e.g., complex polysaccharides, certain viral proteins with repetitive motifs) and multiple surface immunoglobulins are cross-linked, antigen binding alone may be sufficient to induce B-cell activation without cognate (direct cell-cell interaction) help from T cells. In this case, other signals derived from non–T cells, such as cytokines, or from microorganisms, such as bacterial lipoproteins or bacteria-derived DNA containing unmethylated CpG motifs, may enhance antibody responses [826].

## EARLY B-CELL DEVELOPMENT AND IMMUNOGLOBULIN REPERTOIRE FORMATION

### Pro–B Cell and Pre–B Cell Maturation

The pro-B cell is the most immature cell type that is known to have differentiated along the B lineage. Human pro-B cells of the adult bone marrow have a $CD10^{hi}CD19^{-}CD34^{hi}$ surface phenotype. They also express intracellular Pax5, RAG, TdT, and CD79 proteins and undergo D-to-J and then V-to-DJ immunoglobulin heavy chain gene rearrangements [827]. D-to-J heavy chain gene rearrangements also may occur in immature lymphocytes that are not committed to the B lineage, but V-to-DJ rearrangement may be a characteristic feature of committed B-lineage cells. In cases in which the immunoglobulin heavy chain is productively rearranged, it is expressed cytoplasmically and on the B-lineage cell surface as part of the pre–B-cell receptor (BCR) complex, which consists of a surrogate light chain (a VpreB and a λ5/14.1 segment) in association with Ig-α (CD79a) and Ig-β (CD79b) heterodimers. Expression of the pre-BCR complex defines the pre–B-cell stage, and pre-B cells have a $CD10^{hi}CD19^{hi}$ surface phenotype. CD34 expression decreases during the pro–B cell to pre–B cell transition [827].

The heavy chain gene usually rearranges first, initially with a joining of a D segment to a J segment [828]. D-to-J heavy chain gene rearrangement and protein expression are followed by the joining of a V segment to the D-to-J segment. Productive V(D)J rearrangement results in the expression of full-length heavy chain protein in the cytoplasm. In humans, the first easily recognized pre-B cells are those that contain cytoplasmic IgM heavy chains, but no light chains or surface immunoglobulin. The expression of the pre-BCR by the pre-B cell blocks rearrangement of the other heavy chain gene allele (allelic exclusion) and results in proliferation of the pre-B cell for four to five divisions, with concurrent downregulation of RAG and TdT activity [829].

The human pro–B cell to pre–B cell transition depends on the ability to form a functional pre-BCR complex. This transition is blocked by mutations in the Cμ segment of the heavy chain gene, Ig-α, Ig-β, the cytoplasmic Btk tyrosine kinase, or the SLP-65 (also known as B-cell linker) cytoplasmic adapter protein, all of which compromise pre-BCR signal transduction. No known ligand for the human pre-BCR has been defined, and much of its extracellular domain of heavy chain is dispensable for its function. This suggests that the pre-BCR may have ligand-independent basal signaling function [830]. Such ligand-independent function is supported by a structural study that found that the human pre-BCR receptor can dimerize in the absence of any ligand and probably cannot recognize antigens because of steric blockade of the heavy chain binding site by the surrogate light chain [831]. After a burst of cell proliferation, the pre-B cell exits from cycling, upregulates RAG and TdT activity, and promotes immunoglobulin light chain rearrangement.

After the expression of the pre-BCR, a similar process of gene rearrangement subsequently occurs to assemble light chain genes from V and J segments. Allelic exclusion also usually acts at the light chain level, so that only a single type of light chain is produced. κ light chain gene rearrangement usually occurs first, and if κ chain gene rearrangement is productive, this apparently permits λ chain gene rearrangement to proceed [832]. Approximately 60% of human immunoglobulin molecules use κ light chains, and the remainder use λ light chains [833]. If rearrangement and expression of a complete

κ or λ light chain subsequently occur, a functional immunoglobulin molecule is assembled and expressed as surface immunoglobulin. The end result of allelic exclusion is that a B cell usually synthesizes only a single immunoglobulin protein. Compared with the heavy chain, allelic exclusion of immunoglobulin light chains is "leaky" such that 0.2% to 0.5% of circulating B cells express a κ and a λ light chain in their surface IgM [834].

Pre-B cells are first detected in the human fetal liver and omentum by 8 weeks of gestation and in the fetal bone marrow by 13 weeks of gestation [835]. Between 18 and 22 weeks of gestation, pro-B cells or pre-B cells also can be detected in the liver, lung, and kidney [836]. These findings raise the possibility that B-cell lymphopoiesis may occur in these organs in situ at this stage of fetal development. By mid-gestation, the bone marrow is the predominant site of pre–B cell development [837]. B-cell lymphopoiesis occurs solely in the bone marrow after 30 weeks of gestation and for the remainder of life [836]. The neonatal circulation contains higher levels of $CD34^+CD38^-$ progenitor cells that are capable of differentiating into B cells than are found in the bone marrow compartment of children or adults [838]. Cord blood has circulating $IgM^-CD34^+CD19^+Pax\text{-}5^+$ B-cell progenitors cells that span the early B cell, pro–B cell, and pre–B cell stages of development; CD10 expression by these circulating B-cell progenitor cells is variable [839].

## V(D)J Recombination of the Immunoglobulin Gene Loci

Analogous to the β chain of the TCR, the heavy immunoglobulin chain is encoded by V, D, J, and C regions. Approximately 164 V and 37 D gene segments are dispersed over 1100 kb of DNA upstream of the JC region, with nine different J segments located near the C region. Antibody gene rearrangement is required to bring the V, D, and J regions together to form a single exon that is juxtaposed to the C region so that the gene can be expressed (see Fig. 4–9). The same recombinase enzyme complex required for TCR gene rearrangement, including the RAG-1 and RAG-2 proteins, mediates this process. The assembly of the κ and λ light chain genes from multiple potential segments is similar except that D segments are not used.

As in the TCR chains, the CDR1 and CDR2 regions of the antigen-combining site are encoded entirely by the V segments, and the CDR3 is encoded at the junction of the V, D, and J segments. Antibody diversity, similar to TCR diversity, is generated by the juxtaposition of various combinations of V, D, and J segments and by imprecision in the joining process itself owing to exonucleolytic activity, random nucleotide addition by the TdT enzyme, and resolution of hairpin ends as P nucleotides. In the case of the heavy chain gene, D-to-D joining can also occur, and D segments also can rearrange by inversion or deletion. Together, these mechanisms permit a theoretical immunoglobulin repertoire of more than $10^{12}$ specificities to be generated from less than $10^3$ somatic gene segments. For reasons that are unclear, however, immunoglobulin heavy chain V segment usage by immature pre-B cells and antigenically naïve B cells seems to be dominated by relatively few segments [840,841]. Actual immunoglobulin diversity is less than would be predicted if segment usage were completely random. As in the case of the TCR genes, the CDR3 region seems to be the most important source of diversity. Further diversification is possible later in B-cell differentiation by processes known as receptor editing and somatic mutation, which are described later.

## V(D)J Segment Usage of the Fetus and Neonate

The primary or preimmune immunoglobulin repertoire, which consists of all antibodies that can be expressed before encounter with antigen, is determined by the number of different B-cell clones with distinct antigen specificity and is limited during the initial stages of B-cell development in the fetus compared with that in the adult. In the early gestation to mid-gestation human fetus, the set of V segments used to generate the heavy chain gene is smaller than in the adult [842,843]. The V segments are scattered throughout the heavy chain gene locus [844]. Differences in the usage of particular heavy chain D and J segments between the first and second trimesters and term also have been identified [845]. These developmental differences are intrinsic, rather than the result of environmental influences, because they occur in immature B-cell precursors lacking a pre-BCR complex.

By the third trimester, the V and D segment heavy chain gene repertoire of peripheral B cells seems to be similar to that of the adult, although there may be overrepresentation of certain segments [846,847] and underuse of certain JH segments [847]. Certain heavy chain V segments expressed in adult B cells are not found in neonatal B cells [848,849], but it is unlikely that this severely limits the neonatal humoral immune response. Other V segments, such as $V_{H3}$, are present at a greater frequency in the preimmune immunoglobulin repertoire [849,850]. This increased representation may confer on antibody molecules the ability to bind protein A of *S. aureus*, providing some intrinsic protection during the perinatal period.

## CDR3 Length and Terminal Deoxytransferase

The length of the CDR3 region of the immunoglobulin heavy chain, which is formed at the junction of the V segment with the D and J segments, is shorter in the mid-gestation fetus than at birth [851] or in adulthood [852]. This is due, in part, to decreased TdT, which is responsible for N-nucleotide additions. This decreased TdT expression is an intrinsic property of neonatal $CD34^+$ precursor cells not yet committed to the B lineage because in vitro differentiation of B-lineage cells from neonatal $CD34^+$ cells results in lower amounts of TdT than are present in similar cells from adults [853].

Of heavy chain CDR3 regions in fetal B cells, 25% lack N additions, and in the remaining regions, the size of the N-nucleotide additions is smaller than for neonatal or adult CDR3 regions. The CDR3 region is the most hypervariable portion of immunoglobulins, and a short CDR3 region significantly reduces the diversity of the

fetal immunoglobulin repertoire [848]. The CDR3 region of the heavy chain gene remains relatively short at the beginning of the third trimester and gradually increases in length until birth [846,854,855]. Because the CDR3 region is at the center of the antigen-binding pocket of the antibody [856], reduced CDR3 diversity could limit the efficiency of the antibody response. The importance of shortened CDR3 regions by themselves in limiting antibody responses is doubtful, however, because gene knockout mice lacking TdT produce normal antibody responses after immunization or infection [459]. Although a combination of lack of TdT and limitations in V and D usage could limit the ability of the fetal B cells to recognize a full spectrum of foreign antigens, particularly before mid-gestation, such a "hole in the repertoire" has not been documented.

In mice, premature expression of TdT during fetal development achieved by transgenesis was detrimental in adulthood by preventing the appearance of certain natural (preimmune) antibody specificities (e.g., reactive with phosphorylcholine), which increased the susceptibility of the animals to bacterial infection [857]. The combination of decreased TdT activity and the preferential usage of DH7-27, which is the shortest of the DH segments, results in particularly short CDR3 regions in the human fetus and neonate [847]. It has been proposed that these limitations in CDR3 length combined with preferential usage of VH6-1 may be important in generating natural IgM antibody specificities, such as for single-stranded DNA, that may be protective in the fetus and neonate (e.g., by helping eliminate fetal apoptotic cells) [847].

## B-CELL MATURATION, PREIMMUNE SELECTION, AND ACTIVATION

### Receptor Editing, Clonal Deletion, and Clonal Anergy

Immature B cells of the bone marrow that have successfully generated a productive heavy and light chain express these as IgM on the cell surface. A large proportion of these surface immunoglobulins are autoreactive (i.e., they bind with relatively high affinity to molecules on other cell types within the bone marrow microenvironment and peripheral lymphoid organs) [858]. Such self-reactivity and BCR signaling at this stage of development maintains RAG activity with the result that the B cell frequently undergoes a secondary V-to-J light chain rearrangement [859]. This involves V segments located 5′ and J segments that are located 3′ to the current VJ rearrangement. If this eliminates surface immunoglobulin autoreactivity, the lack of BCR-mediated cell signaling turns off RAG activity, and the B cell enters into the circulation as a new emigrant (transitional) B cell to complete its maturation. If not, additional light chain rearrangement can occur.

Analysis of patients with genetic immunodeficiencies of signaling pathways involved in TLR recognition unexpectedly found an accumulation of autoreactive B cells, indicating that IRAK-4–dependent and MyD88-dependent signaling is involved in the receptor editing process [860]. Replacement of V heavy chain gene segments with previously unrearranged upstream V segments is also possible [861], but this is a rare form of editing for human B cells. Most immature autoreactive B cells can be converted to nonautoreactivity by receptor editing, allowing most B cells with productive immunoglobulin heavy chain rearrangements to contribute to the final repertoire.

The persistently autoreactive B cells are probably eliminated by a process of clonal deletion, which involves apoptosis induced by strong BCR signaling [858], or anergy, in which the B cells are functionally inactivated. A more recent study [862] has identified a distinct naïve B-cell subset of $IgD^+IgM^-CD27^-$ cells that has the BCR antigen specificity (predominantly autoreactive) and intracellular signaling characteristics (reduced capacity to increase intracellular calcium and increase tyrosine phosphorylation) indicative of anergic B cells. In healthy adults, these $IgD^+IgM^-$ anergic B cells constitute about 3% of all circulating B cells.

In contrast to $IgM^+$ adult B cells in the peripheral lymphoid organs, most of which also express surface IgD, first-trimester fetal B cells express IgM without IgD [863]. Such $IgM^+IgD^-$ B cells constitute a transitory stage between pre-B cells and mature $IgM^+IgD^+$ B cells. Murine studies have shown that exposure of transitional $IgM^+IgD^-$ B cells to antigens, including antigens found in the adult bone marrow, results in clonal anergy rather than activation [864]. The susceptibility of transitional $IgM^+IgD^-$ cells to clonal anergy maintains B-cell tolerance to soluble self-antigens present at high concentrations. Antigen exposure in utero may induce B-cell tolerance, rather than an antibody response, and may account for the observation that early congenital infection sometimes results in pathogen-specific defects in immunoglobulin production. In some cases, such as congenital mumps, these defects may occur despite apparently normal T-cell responses [799], suggesting a direct inhibitory effect on B-cell function.

An analysis of productive and nonproductive λ light chain gene repertoire of the human fetal spleen at 18 weeks of gestation found evidence of receptor editing, indicating that B cells encounter self-antigens that mediate negative selection in early ontogeny [865,866]. Similar findings apply to the κ light chain repertoire of cord blood B cells [866]. Together, these findings suggest that the preimmune fetal immunoglobulin repertoire is significantly shaped by self-antigens.

### New Emigrant (Transitional) versus Fully Mature Naïve B Cells

The initial expression of surface immunoglobulin by B-lineage cells is in the form of IgM and IgD isotypes. This is the result of alternative mRNA splicing of the exons of the heavy chain gene. In adults, these $IgM^{hi}IgD^{hi}$ transitional B cells can be identified in the bone marrow and circulation by their high levels of expression of CD24, CD38, CD5, and CD10 and low levels of Bcl-2 and the ABCB1 transporter [867–870]. These cells also are enriched for Ki67 staining, indicating they have recently undergone proliferation. CD5, CD10, CD24, CD38, and Ki67 staining decline, and ABCB1 is upregulated as new emigrant B cells mature into naïve B cells

[867]. Analogous to T-lineage cells, these circulating transitional B cells can be considered as recent bone marrow emigrants (new emigrants) that undergo a post–bone marrow phase of peripheral maturation into fully mature naïve B cells. Murine studies indicate that transitional B cells mainly undergo further maturation into naïve B cells in the spleen. Although the sites of this maturation process in humans is unknown, it seems to be B-cell activating factor of the tumor necrosis factor family (BAFF)–dependent [871].

The maturation of new emigrant B cells into fully mature, antigenically naïve B cells includes negative selection of B cells with autoreactive BCRs that have entered into the periphery and that have somehow escaped central tolerance mechanism in the bone marrow. Although the mechanisms involved in this secondary checkpoint for B-cell tolerance remain poorly understood, it may involve, at least in part, the death of autoreactive B cells because of their greater dependence on BAFF for survival than nonautoreactive B cells [860]. This peripheral tolerance checkpoint also seems to require CD4 T cell–derived signals, as the proportion of B cells that have autoreactive BCRs is significantly increased in antigenically naïve B cells of patients with genetic defects affecting CD40 ligand or MHC class II [872]. It is plausible that the increased frequency of autoreactive naïve B cells in patients with MHC class II deficiency may reflect decreased numbers of MHC class II–restricted $CD25^+$ CD4 Tregs in these individuals [860].

New emigrant B cells may also be subject to the influence of positive selection, which in mice can influence whether a B cell differentiates into particular B-cell subsets, such as follicular B cells versus marginal zone B cells, which are discussed subsequently. Positive selection requires an intact BCR complex and presumably involves some interaction of the antigen-combining site of the BCR with self-molecules or tonic signaling by the BCR complex [830], or both. In contrast with positive selection of thymocytes, which involves mainly cortical epithelial cells that present self-peptides, the nature and cellular sources of the ligands involved remain obscure. Evidence for positive selection of B cells in the human in fetal life comes from comparisons of the immunoglobulin repertoire of pre-B cells and transitional B cells versus the immunoglobulin repertoire of mature naïve B cells [873].

## Follicular B-Cell Maturation

New emigrant B cells that escape negative selection and have undergone positive selection are directed by poorly understood pathways to become fully mature naïve $IgM^{hi}IgD^{hi}CD27^{lo/-}ABCB1^+$ follicular B cells [867,874]. Follicular B cells include most of the B cells that are involved in adaptive immune responses to T-dependent antigens, such as proteins and protein-carbohydrate conjugates, and are the predominant naïve B-cell subset of cells in the circulation or secondary lymphoid tissue. Marginal zone and B-1 B cells, which have distinct roles from follicular B cells in immunity, are discussed separately.

Similar to naïve T cells, the naïve B-cell subset has a very slow rate of turnover in vivo [867,875] and expression of CXCR4, CXCR5, and CCR7, which promotes their recirculation between the follicles of the peripheral lymphoid organs, including the spleen, lymph nodes, and Peyer patches, and the blood and lymph [876]. The CXCR5 chemokine receptor recognizes CXCL13, which is produced within the follicles and promotes entry into and retention by the follicle [877]. Other B-cell functions that concurrently mature include a decreased tendency to undergo apoptosis after BCR engagement, an increased responsiveness to T-cell help (e.g., CD40 ligand and soluble cytokines, such as IL-21), increased expression of CD86, and maturation of intracellular signaling in response to BCR engagement. In addition to secondary lymphoid tissue, follicular B cells may also home to the perisinusoidal areas of bone marrow, which are also enriched in DCs that may provide important signals for B-cell survival. Perisinusoidal bone marrow B cells are poised to respond rapidly to blood-borne antigens, such as those derived from *Salmonella*, and produce antigen-specific IgM in a T-independent manner [878].

## Fetal and Neonatal B-Cell Frequency and Surface Phenotype

B cells expressing surface IgM are present by 10 weeks of gestation [835]. The frequency of B cells in tissues rapidly increases, so that by 22 weeks of gestation, the proportion of B cells in the spleen, blood, and bone marrow is similar to that in the adult [863]. The concentration of B cells in the circulation is higher during the second and third trimesters than at birth and declines further by adulthood [879].

Circulating neonatal B cells are highly enriched in the new emigrant cell subset [867] based on their $IgM^+IgD^+CD24^+CD38^+ABCB1^-$ surface phenotype and high levels of CD5, CD10, and Ki67. Approximately 70% to 75% of cord blood B cells are new emigrants, and 25% to 30% are fully naïve B cells [867,880]. $CD27^+$ B cells, which include most memory B cells in adults, are low to undetectable in cord blood, consistent with the antigenic naïvete of the healthy newborn. Together, these findings account for earlier reports of higher levels of IgM, CD5, CD10, and CD38 surface expression and lower levels of CD11a, CD21, CD44, CD54 (ICAM-1), and L-selectin [881–886] in cord blood B cells than in the adult circulation Most fetal spleen B cells express CD5 and CD10 [827,887], indicating that new emigrant B cells predominate in the spleen. As for RTEs, the predominance of new emigrant B cells in the fetus and neonate is consistent with the likely high level of production of B cells at this age.

Unfractionated neonatal B cells and $CD27^-/IgM^+$ adult B cells of the circulation have similar levels of surface IgD, CD19, CD22, CD23, CD40, CD44, CD80, CD81, CD86, CCR6, and CXCR5 [881,884–886,888–891], but neonatal B cells may have modestly lower levels of CCR7 [881]. The frequency of new emigrant B cells in the circulation gradually declines with age.

# B-CELL ACTIVATION AND IMMUNE SELECTION

As with T cells, B cells receive additional regulatory signals from the engagement of surface molecules other than the BCR that act as either costimulatory or inhibitory

molecules. Of the costimulatory molecules, a complex consisting of CD19, CD21, and CD81 is best defined [892,893]. CD21, also known as complement receptor 2, binds the CD3d fragment of the C3 complement component. CD19 transmits intracellular activation signals after complement binding to CD21. Effective signaling after engagement of the BCR requires that key proximal signaling molecules are appropriately compartmentalized by means of lipid rafts, which are specialized cholesterol and glycosphingolipid microdomains of the plasma cell membrane [894]. In this context, CD81 may be particularly important for partitioning CD19/CD21/BCR complexes into lipid rafts so that antigen engagement is effective for B-cell activation [895].

The encounter of naïve B cells with antigen recognized by the surface immunoglobulin triggers their activation and proliferation under appropriate conditions. In contrast to αβ T cells, which recognize antigen in the form of processed fragments bound to the antigen-presenting grooves of MHC molecules, most B-cell surface immunoglobulins recognize antigen in a nondenatured form so that antigen recognition is highly sensitive to any alterations in the three-dimensional shape, such as post-translational modifications. Naïve B cells may encounter such nondenatured antigens presented by cDCs shortly after the B cell enters the lymph node or spleen via high endothelial venules before it enters the follicle [896]. Alternatively, naïve B cells entering the follicle may have soluble antigens shuttled to them by other B cells [897] or presented by follicular DCs, resident nonhematopoietic cells of the follicle. The relative importance of these different mechanisms for antigen presentation to naïve B cells likely varies depending on the nature of the antigen and the sites at which it is acquired by APCs.

B cells are activated to proliferate and differentiate into antibody-secreting cells after surface immunoglobulin binds antigen. The surface immunoglobulin molecule is invariably associated with the nonpolymorphic membrane proteins, Ig-α (CD79a) and Ig-β (CD79b), which, in conjunction with surface immunoglobulin, constitute the BCR. Ig-α and Ig-β, which are structural and functional homologues of the CD3 complex proteins, are expressed as disulfide-linked heterodimers, and contain ITAM motifs in their cytoplasmic tails. ITAMs act as docking sites for signaling molecules, such as the Lyn and Syk tyrosine kinases, that ultimately signal to alter gene transcription and initiate an activation program.

As with naïve T cells, activation of naïve B cells by BCR engagement has a high signal threshold compared with that of memory cells, a feature that may prevent inappropriate activation by low-affinity self-antigens. This is followed by activation of the phospholipase C/protein kinase C, Ras, and NFκB/Rel pathways that ultimately alter gene transcription. The CD19 molecule also has a cytoplasmic domain that serves as a docking site for several tyrosine kinases that provide costimulation when the CD19/CD21 complex is engaged by complement fragments, such as C3d. Engagement of CD40 on the B cell by CD40-ligand on the CD4 T cell also contributes to activation by inducing NF-κB/Rel transcription factor pathway. In the case of protein antigens, BCR engagement is followed by antigen internalization and entry into the MHC class II antigen presentation pathway. Activation also increases B-cell expression of CCR7, which promotes B-cell movement toward the outer border of the T-cell zone [898], and of OX40 ligand (TNFSF4) and CD30 ligand (TNFSF8) [899], which can provide T-cell costimulation.

## Negative Regulation of B-Cell Signaling

As for T cells, the activation of B cells is tightly regulated, and several surface molecules provide inhibitory signals that ensure that full activation requires overcoming a high signaling threshold, limiting the risk of activation by low-affinity autoantigens. These include CD22 and CD72, both of which contain intracellular ITIM motifs that when phosphorylated recruit tyrosine phosphatases (e.g., SHP-1 and SHP-2) and inositol phosphatases (e.g., SHIP-1) that limit B-cell activation signals via the BCR and costimulatory molecules (e.g., CD21) [900]. In addition, B cells express FcRγIIb, an ITIM-containing Fc receptor that mediates negative signaling when antibody simultaneously engages this receptor via its Fc moiety and binds to antigen on the BCR surface [120]. Surface expression of FcγRIIb is reduced on neonatal B cells [885,901], possibly rendering them less subject to the inhibitory effect of antigen-antibody complexes.

## CD4 T-Cell Help for Naïve B-Cell Activation

For B cells to be activated effectively and to produce antibody against protein and protein-carbohydrate conjugate antigens requires help from CD4 T cells in most cases. This help is in the form of soluble cytokines, such as IL-21 [868], and of cell surface–associated signals, such as CD40 ligand, which is transiently expressed on the surface of activated CD4 T cells [524,525]. In T cell–dependent activation, antigenically naïve CD4 T cells probably are first activated by DCs independently of B cells [902]. CD4 T cells that are activated by DCs bearing antigenic peptide–MHC class II complexes and CD80-CD86 costimulatory molecules express CD40 ligand, OX40, ICOS, and CXCR5 [903]. These activated CD4 T cells may leave the lymphoid organ to become effector or memory T cells or become CD4 T cells specialized to provide help to B cells.

CD4 T cells destined to leave the lymphoid organ and to enter sites of tissue inflammation and participate in inflammatory responses (e.g., $T_H1$ cytokine secretion) are P-selectin$^{hi}$, CXCR3$^+$, and CXCR5$^-$. By contrast, CD4 T cells that are retained in the lymph node and that eventually enter the follicle as $T_{FH}$ cells are P-selectin$^-$ and CXCR3$^-$, but express CXCR5. This CXCR5 expression promotes movement of these CD4 T cells to the outer border of the T-cell zone, to contact antigen-activated B cells at the edge of the follicular zone [877]. Here, CD4 T-cell activation is reinforced by recognition of antigenic peptides displayed on MHC class II molecules of the B cell, and the interaction of CD40 ligand and OX40 on the T cell with CD40 and OX40 ligand on the B cell enhances B-cell activation. OX40 engagement of the CD4 T cell also promotes its differentiation into a $T_{FH}$ cell by increasing or helping retain the expression of CXCR5. These CXCR5$^{hi}$ CD4 T cells enter into the follicle, where they provide help to B cells as $T_{FH}$

cells by expressing CD40 ligand, secreting IL-21 and other cytokines, and providing ICOS-dependent B-cell costimulation [551].

As discussed earlier, surface levels of CD40 ligand by circulating neonatal CD4 T cells is reduced compared with that by naïve adult CD4 T cells. Although this reduction could limit B-cell help for antibody responses, it is unclear if such reductions apply to $T_{FH}$ cells of the neonate and infant in vivo.

### B-Cell Selection in Germinal Centers of the Follicle

During the initial immune response, most antigenically naïve follicular B cells are derived from clones expressing antibody variable regions with relatively low affinity for antigen. As in the case of the TCR, activation through the BCR is not an all-or-none phenomenon. High-affinity binding to IgM of the BCR may allow B-cell proliferation to occur in the absence of any T-cell help, whereas lower affinity binding may result in proliferation only in the presence of additional T cell–derived signals. Antigen-specific B cells proliferate strongly within the B-cell follicle, leading to the formation of germinal centers. The more avidly the B cell binds antigen, the stronger is the stimulus to proliferate. The major source of antigen for triggering the extensive B-cell proliferation of the germinal center may be provided by antigen complexed with antibody bound to Fc receptors on follicular DCs, although this point is controversial [904]. The follicular DC is a nonhematopoietic cell type that seems to have the unusual capacity to bind antigen-antibody complexes for long periods on their cell surface. As already noted, follicular B cells may also receive antigen from other B cells that enter into the follicle or by their interactions with DCs on entry into the lymph node from the circulation [904]. True germinal centers in the spleen and lymph nodes are absent during fetal life, but appear during the first months after postnatal antigenic stimulation [905].

### Somatic Hypermutation

Immunoglobulin variants are generated among germinal center B cells by the process of somatic hypermutation, in which immunoglobulin genes accumulate apparently random point mutations within productively rearranged V, D, and J segments. These variants undergo a selection process favoring B cells that bear surface immunoglobulin with high affinity for antigen. Such high-affinity immunoglobulin provides high levels of BCR signaling, favoring germinal center B-cell survival, rather than a default pathway of apoptosis. Somatic hypermutation requires an activation-induced cytidine deaminase (AID), which apparently is expressed only by germinal center B cells. AID deaminates deoxycytidine residues in single-stranded DNA to deoxyuridines, which are processed by DNA replication, base excision, or mismatch repair to restore normal base pairing between the two DNA strands, resulting in somatic hypermutation [525]. The effects of the mutator are focused on the variable region of immunoglobulin and its immediate flanking sequences. The peak of somatic mutation is approximately 10 to 12 days after immunization with a protein antigen [906]. Somatic mutation is an important means for increasing antibody affinity, but it may also result in the acquisition of autoimmunity. Human B cells with newly acquired autoreactivity as a result of somatic mutation are not subject to receptor editing or other tolerance mechanisms [907].

Most neonatal and fetal immunoglobulin heavy chain gene variable regions seem not to have undergone somatic mutation [849,851], consistent with the predominance of antigenically naïve new emigrant B cells in the fetus and neonate. By contrast, somatic mutations are detectable in some neonatal B cells expressing IgG or IgA transcripts [855], and the mutational frequency per length of DNA is similar to that of adult B cells. In contrast to follicular B cells, in which somatic hypermutation seems to occur only in germinal centers, a subset of marginal zone $IgM^+IgD^+CD27^+$ B cells shows somatic hypermutation in the fetus before the appearance of germinal centers. In this context, extrafollicular somatic hypermutation seems to serve as a means to broaden the preimmune immunoglobulin repertoire of this B-cell subset.

## MEMORY B CELLS

Germinal center B cells that receive appropriate survival signals leave the germinal center to persist as memory B cells. Most follicular memory B cells are $CD27^{hi}$ and have undergone isotype switching so that they are $IgM^-IgD^-$ [908]. They also lack the ABCB1 naïve B-cell marker [867]. The turnover of memory B cells is approximately fivefold higher than naïve B cells based on their high levels of labeling in vivo and expression of the Ki67 antigen [867,875]. A fraction of memory B cells are $CD27^-ABCB1^-$ cells, most of which express BCRs that have undergone isotype switching to IgG1 or IgG3, but not to IgG2 or IgA [867]. Human memory B cells are also heterogeneous in their expression of CD19, CD21, CD24, CD25, CD38, and FcRH4 (an inhibitory receptor), and these markers can be used to define additional memory B-cell subsets [909].

The engagement of CD40 on germinal center B cells by CD40 ligand on T cells is absolutely required for memory B-cell generation. Efficient memory B-cell generation requires the binding by CD21 on B cells of C3 complement components, such as C3d [892]. When a memory B cell is generated, further somatic mutation of its immunoglobulin genes apparently does not occur. Memory B cells enter the recirculating lymphocyte pool, where they preferentially colonize the skin and mucosa, sites that are likely to have direct contact with antigen, and the marginal zone of the spleen, where they are poised to respond to blood-borne antigens. When memory B cells are generated, they seem to persist indefinitely even in the absence of any subsequent exposure to the inciting antigen [910]. Memory B cells are typically not detectable in the circulation of the healthy fetus or neonate, consistent with limited B-cell exposure to foreign antigens in utero.

## B CELLS AS ANTIGEN-PRESENTING CELLS

B cells express all of the proteins of the MHC class II antigen presentation pathway and can serve as APCs to CD4 T cells. Memory B cells are probably more effective

than antigenically naïve B cells in simulating CD4 T cells because they constitutively express higher surface levels of CD80 or CD86 molecules that provide T-cell costimulation. Interactions between ICOS on the T cell and ICOS-ligand on the B cell may also be essential for inducing naïve CD4 T cells to differentiate into $T_{FH}$ cells [551]. Surface immunoglobulin–protein complexes internalized from the cell surface are probably the preferential source of protein for antigenic peptides presented to T cells by B cells. The internalized proteins are degraded to peptides, which can be presented back on the B-cell surface bound to MHC class II molecules. Because the surface immunoglobulin–antigen interaction is of high affinity, B-cell antigen presentation theoretically permits CD4 T cells to be activated at relatively low concentrations of antigen. The observation that CD4 T-cell $T_H1$ immunity is intact in patients with X-linked agammaglobulinemia is consistent, however, with the notion that DCs, rather than B cells, play the central role in MHC class II antigen presentation [911].

Circulating neonatal B cells have lower levels of MHC class II than observed for adult splenic B cells [912], but proliferate at least as well as adult splenic B cells after MHC class II engagement [912]. Circulating third-trimester fetal and adult B cells were reported to express similar amounts of MHC class II [913]. There is limited information, however, regarding the capacity of fetal and neonatal B cells to serve as APCs for CD4 T cells.

## SWITCHING OF IMMUNOGLOBULIN ISOTYPE AND CLASS AND ANTIBODY PRODUCTION

### Isotype Switching

Human B cells produce five isotypes of antibody: IgM, IgD, IgG, IgA, and IgE. The IgG and IgA isotypes can be divided into the IgA1 and IgA2 and the IgG1, IgG2, IgG3, and IgG4 subclasses. During their process of differentiation into plasma cells, B cells are able to change from IgM to other antibody isotypes without changing antigen specificity (see Fig. 4–9). With the exception of IgD expression, this switching usually involves isotype recombination, the genetic replacement of the IgM-specific portion of the constant region (Cμ) of the heavy chain with a new isotype-specific gene segment. As in V(D)J recombination, the intervening DNA is excised as a large circle. Isotype recombination is mediated by switch regions that are positioned immediately upstream of each of the isotype-specific C regions, with the exception of IgD. Successive multiple isotype switching by a single B cell also can occur (e.g., IgM to IgA to IgG to IgE).

Genetic studies of hyper-IgM syndrome, in which there is a generalized block in isotype switching from IgM to other isotypes, have revealed that the process requires interactions between CD40 ligand on the T cell and CD40 on the B cell, the AID gene product (which also is required for somatic hypermutation), and the uracil N-glycolyase (UNG) enzyme [525]. There are also CD40-independent signals for such switching, such as provided by TLR9 found in the B-cell endosomal compartment binding to unmethylated CpG DNA (e.g., derived from bacteria) [914]. The molecular biology of switch recombination is complex, but similar to V(D)J recombination, involves double-stranded DNA breaks, in this case induced by the sequential action of AID, UNG, and an apurinic/apyrimidinic endonuclease [915], rather than the RAG proteins. These breaks are repaired by the NHEJ proteins involved in V(D)J recombination and additional proteins [916]. Secreted cytokines derived from T cells or other cell types play an important role in promoting or inhibiting switching to a specific isotype. IL-4 or IL-13 is absolutely required for isotype switching to IgE, a process that can be inhibited by the presence of IFN-$\gamma$ [917]. In some instances, hormones also may play a role in isotype switching. Vasoactive intestinal peptide in conjunction with CD40 engagement can induce human B cells to produce high levels of IgA1 and IgA2 [918].

During a primary immune response, isotype switching by B cells seems to occur shortly after these cells enter into the follicle [919]. These B cells may have received the requisite T cell–derived signals (i.e., cytokines and CD40 ligand) during their interaction with T cells at the border between the follicle and T-cell zones. Switch recombination after primary immunization is evident in peripheral lymphoid tissue 4 days after immunization with protein antigen and peaks at 10 to 18 days [920]. Switch recombination also is triggered during memory B-cell responses, is detectable within 24 hours of secondary immunization, and peaks at 3 to 4 days [921].

### Generation of Plasma Cells and the Molecular Basis for Immunoglobulin Secretion

Some activated B cells become plasmablasts and migrate to extrafollicular regions of the lymph node or spleen, where they become short-lived plasma cells that mainly produce IgM. Differentiation of these plasma cells does not require, and may be inhibited by, the CD40 ligand–CD40 interaction. In the absence of CD40 engagement, germinal center B cells that have survived the selection process probably differentiate to memory B-cell populations. Lanzavecchia and colleagues [910] suggested that memory B cells have a low threshold to become relatively long-lived plasma cells in an antigen-dependent manner, and that this antigen-independent conversion and antigen-independent division within the memory B-cell pool accounts for the typically lifelong maintenance of serologic (antibody) memory in humans after natural infection. In this case, the level of memory B cells attained after infection or vaccination would be the main determinant of antibody levels. Human memory B cells can differentiate into plasma cells in response to antigen-independent mechanisms, such as exposure to oligonucleotides containing unmethylated CpG DNA or activated T cells [922]. Such polyclonal activation of memory B cells has been proposed to maintain levels of specific antibody for a lifetime after memory B-cell responses have been generated [910].

Plasma cell generation from B cells involves the downregulation of the Bc16 protein and the upregulation of the B lymphocyte–induced maturation protein-1 (BLIMP1) and X box binding protein 1 (XBP1) transcription factors [923]. XBP1 drives B cell differentiation into a fully

mature plasma cell that is capable of extremely high levels of antibody production [924]. The membrane-bound form of immunoglobulin is slightly longer than the secreted form and contains a carboxy-terminal region that anchors the molecule in the cell membrane. Plasma cell differentiation results in a switch to a secretory form of immunoglobulin that lacks this membrane-anchoring segment and the loss of surface immunoglobulin expression as a result of a change in splicing of the heavy chain mRNA. Plasma cells, rather than mature B cells, account for most of the secreted antibody during primary and secondary immune responses.

B cell differentiation into plasma cells is also likely accompanied by increases in CXCR4 expression, which helps target these cells to niches in the bone marrow containing stromal cells that secrete the CXCR4 ligand SDF-1 [925]. Plasma cells are concentrated in peripheral lymphoid tissue, liver, and bone marrow and in lymphoid tissue of the gastrointestinal and respiratory tracts.

## Isotype Switching and Immunoglobulin Production by Fetal and Neonatal B Cells

Early in vitro studies of neonatal immunoglobulin production used pokeweed mitogen, a polyclonal activator of T cells and B cells. In this system, immunoglobulin production was low compared with immunoglobulin production in adults, and mixing experiments suggested that neonatal T cells acted as suppressors of immunoglobulin production by either adult or neonatal B cells. Further fractionation of the T-cell populations in this assay suggested that in the absence of memory/effector T cells, antigenically naïve ($CD45RA^{hi}CD45RO^{lo}$) $CD4^+$ T cells of either the neonate or the adult acted as suppressors of antibody production [628]. The relevance of the suppression to neonatal B-cell responses in vivo is unclear, however. Priming of neonatal or adult antigenically naïve CD4 T cells in vitro resulted in their acquisition of a $CD45RA^{lo}CD45RO^{hi}$ phenotype and, concurrently, an ability to enhance rather than suppress pokeweed mitogen–induced immunoglobulin production [628]. This increased capacity for B-cell help probably reflects the fact that priming of naïve T cells enhances expression of CD40 ligand and cytokines needed for T cell–dependent help for B-cell responses.

When B cells are activated by exogenous cytokines (e.g., IL-4, IL-10, or cytokine-containing supernatants from activated T cells) and a cellular source of CD40 ligand (e.g., CD40 ligand expressing fibroblasts) or EBV infection, neonatal B-cell production of IgM, IgG1, IgG2, IgG3, IgG4, and IgE is similar to that in adult antigenically naïve B cells [608,926–928]. This is not unexpected because neonatal B cells are highly enriched in new emigrant B cells [867,869,870,880], and this B-cell subset in adults and fully mature naïve B cells are similarly efficient in undergoing isotype switching and secreting switched antibody [880]; neonatal B cells treated under these conditions also have robust signaling based on tyrosine phosphorylation of STAT6 by IL-4 and of STAT3 by IL-21 and secrete high levels of IgE [929].

Isotype switching is associated with cell division, and neonatal and adult B cells show a similar acquisition of switching starting after the third cell division [930]. Pre-B cells have the capacity for isotype switching even during fetal ontogeny. Isotype switching and IgE and IgG4 production by fetal B and pre-B cells at 12 weeks of gestation can be induced in vitro [931]. IgA1 and IgA2 are produced in similar amounts by antigenically naïve fetal and adult B cells on stimulation with anti-CD40 antibody and vasoactive intestinal peptide hormone. Fetal pre-B cells also can synthesize IgA under these conditions [917]. When human fetal or neonatal B cells develop in, or are adoptively transferred into, SCID mice, they are capable of isotype switching and immunoglobulin production if appropriate T cell–derived signals are present [767,932,933].

Other studies suggest that isotype switching and antibody production by fetal and neonatal B cells is limited compared with these processes in antigenically naïve ($IgM^+IgD^+$) adult B cells. Durandy and colleagues [605] found that IgM, IgG, and IgE production by fetal B cells at mid-gestation was substantially lower than that of neonatal or adult B cells, suggesting an intrinsic hyporesponsiveness to CD40 or cytokine receptor engagement or both. Neonatal B cells produce substantially less IgA than adult naïve B cells in the presence of adult T cells stimulated by anti-CD3 mAb (as a source of CD40 ligand) and exogenous cytokines, such as IL-10 [934]. These limitations of fetal and neonatal isotype switching and antibody production probably reflect intrinsic limitations of B-cell function, particularly when T-cell help may be limited. Such limited production is not due to decreased activation or proliferation because neonatal B cells proliferate normally in response to engagement of CD40 or surface IgM or both [886].

Neonatal T cells activated for a few hours provide less help for neonatal B-cell immunoglobulin production and isotype switching than do similarly treated adult T cells [608]. Because this help probably is through CD40 ligand, reduced expression of CD40 ligand (or similar activation-induced molecules) by naïve neonatal T cells in the first few hours after activation may limit fetal and neonatal B-cell immune responses. Whether decreased neonatal DC function also contributes to diminished B-cell responses has not been determined.

Between 8 and 11 weeks of gestation, transcripts for IgA and IgG can be detected in the liver [935], and synthesis of IgM and IgG has been detected by 12 weeks of gestation in fetal organ cultures [936]. By 16 weeks of gestation, fetal bone marrow B cells expressing surface immunoglobulin of all heavy chain isotypes are detectable [937]. Immunoglobulin-secreting plasma cells are detectable by week 15 of gestation, and plasma cells secreting IgG and IgA are detectable by 20 and 30 weeks of gestation [938]. The stimulus for isotype switching during fetal development is unclear because in the adult, isotype switching typically occurs in response to B-cell activation by foreign protein antigens. These findings in bone marrow contrast with a flow cytometric study, in which nonspecific binding was carefully excluded, and neonatal B cells expressing surface IgG or IgA were below the limit of detectability (i.e., <1% of circulating B cells) [939].

Generally, neonatal B cells can differentiate into IgM-secreting plasma cells as efficiently as adult cells.

T cell–dependent immunoglobulin production by neonatal B cells is more readily inhibited, however, by agents that increase intracellular cAMP, such as prostaglandin $E_2$ [940].

## MARGINAL ZONE AND $IgM^+IgD^+CD27^+$ B CELLS

The human spleen has distinct anatomic sites that may play specialized roles in the production of antibody against blood-derived particulate antigens and purified repetitive carbohydrate antigens. Important examples of such carbohydrate antigens are the capsular polysaccharides of pathogenic bacteria, such as *S. pneumoniae*, *Neisseria meningitidis*, and *H. influenzae*. Antigens and leukocytes enter the spleen through vascular sinusoids located in the red pulp that are in proximity to the marginal zone area. The white pulp area contains periarteriolar sheaths of lymphocytes, mainly T cells, and periarteriolar follicles, which are mainly B cells. These are surrounded by a microanatomic site known as the marginal zone that contains loose clusters of B cells, DCs, macrophages, and some CD4 T cells and that are in direct contact with the blood.

B cells of the human marginal zone of the adult spleen are predominantly $IgM^+IgD^+CD27^+$ and have BCRs encoded by somatically mutated immunoglobulin genes. B cells with this phenotype are of interest because they seem to mediate most of the IgM antibody response to unconjugated polysaccharides [941], which are T-independent type II antigens. In contrast to the murine marginal zone B cells, which do not seem to recirculate when they arise in the spleen from new emigrant B cells, the human adult circulation and tonsils have substantial numbers of B cells of a similar phenotype of those in the marginal zone. Somatic hypermutation is thought to be limited to B cells undergoing activation in germinal centers; however, $IgM^+IgD^+CD27^+$ B cells retain their somatic hypermutated immunoglobulin receptors in genetic disorders that prevent germinal center formation, such as deficiency of CD40, CD40 ligand, ICOS, and SH2D1A (SAP) [525,942], arguing for the existence of a germinal center–independent pathway.

Marginal zone B cells have unique phenotypic and functional properties that may be important in their production of IgM in response to blood-borne particulate antigens, such as bacteria, in addition to their having direct access to the blood and to circulating DCs that may bear these antigens [943]. Compared with naïve follicular B cells, marginal zone B cells express higher levels of CD21, which may facilitate the binding of C3d-coated blood-borne antigens, such as encapsulated bacteria [944]. Marginal zone B cells are also more readily activated by non-BCR signals, such as LPS, and more rapidly become effector cells than naïve follicular B cells after activation. This enhanced reactivity may be important in their being able to respond to purified polysaccharide antigens in the absence of T-cell signals [945]. Marginal zone B cells also seem "poised" to differentiate rapidly into $IgM^+$ plasmablasts [943] because of their constitutive expression of BLIMP-1, which promotes plasma cell differentiation [946].

The hyposplenic or asplenic state invariably compromises the human antibody response to purified polysaccharides, such as capsular polysaccharide components of the 23-valent pneumococcal vaccine. Splenic marginal zone B cells may be required for the generation of antibody responses to purified polysaccharide antigens, accounting for the loss of these responses with splenectomy. This loss could also be due to the removal of other cell types, however, or a specialized splenic microenvironment required for the purified polysaccharide antigens. This immune response does not absolutely require T-cell help (see section on development of B-cell capacity to respond to T cell–dependent and T cell–independent antigens). Immunization with T-independent antigens before human splenectomy maintains the capacity of the immune system to respond to these antigens subsequently [947]. This finding suggests that the activation of splenic B cells recognizing polysaccharide antigens may result in their migration and persistence in other lymphoid organs. The pathways by which capsular polysaccharide antigens reach the marginal zone are unknown, and the role that human marginal zone DCs or macrophages play in activating marginal zone B cells to produce antibody to purified polysaccharides is poorly understood. How human splenic marginal zone B cells involved in the response to purified polysaccharide antigens differentiate from naïve precursors also is unclear.

### Marginal Zone B Cells of the Fetus and Neonate

$IgM^+IgD^+CD27^+$ B cells are detectable at birth in relatively low numbers and gradually increase to adult levels by approximately 2 to 3 years of age. $IgM^+IgD^+CD27^+$ B cells have a diverse immunoglobulin repertoire similar to that of conventional naïve B cells, rather than a more skewed repertoire typical for memory B cells that have undergone isotype switching. Together, these observations argue that $IgM^+IgD^+CD27^+$ B cells are distinct from conventional follicular B cells in that somatic hypermutation occurs outside of germinal centers and generates a mutated immunoglobulin sequence as part of a preimmune mechanism. Consistent with this idea, $IgM^+IgD^+CD27^+$ B cells with somatically mutated immunoglobulin genes are detectable in the circulation, liver, mesenteric lymph nodes, spleen, and bone marrow by 14 weeks of gestation [948], even though germinal centers and presumably antigen exposure are absent until after birth.

Somatic hypermutation of this fetal B-cell population may occur in the mesenteric lymph nodes and liver because these tissues express the AID enzyme required for this process, whereas fetal spleen tissue does not. The somatic hypermutation does not seem to require T-cell help because it occurs normally in human $IgM^+IgD^+CD27^+$ B cells developing from human HSCs in RAG-2/common $\gamma$ chain knockout mice, which lack T cells [948]. Although the marginal zone of the spleen does not achieve its mature configuration until about 2 years of age, $IgM^+IgD^+CD27^+$ B cells have been identified in the marginal zone at 8 months of age [949]. If the $IgM^+IgD^+CD27^+$ marginal zone B-cell population is required for the responses to unconjugated polysaccharides, the inability of infants younger than 2 years of age to respond to such vaccines is not accounted for by an absence of this splenic B-cell subset. Rather, the

deficiency is likely to be due at least in part to a qualitative defect in this IgM+IgD+CD27+ B-cell subset or in the APCs involved in its activation, such as the macrophages and DCs of the marginal zone. One such factor may be the reduced expression on B cells from preterm and, to a lesser degree, term neonates of receptors for BAFF and APRIL (a proliferation-inducing ligand) [950]. These cytokines are produced by APCs, are similar in structure to CD40 ligand, and are essential for T-independent responses to polysaccharide antigens. It is unclear, however, whether this observation also applies to the marginal zone B-cell subset of neonates.

## B-1 CELLS AND NATURAL IgM

In mice, a B-cell subset that has been termed B-1 has a distinct tissue distribution restricted largely to the peritoneal and pleural cavities and special functional features, such as a tendency for polyreactive antibody specificities, particularly of the IgM isotype, compared with the bulk of B cells, which are termed B-2. The murine B-1 subset can be divided further into B-1a cells, in which CD5 is expressed on the cell surface, and B-1b cells, in which CD5 expression is limited to the RNA level. The B-2 lineage includes most peripheral B cells of the secondary lymphoid organs and most marginal zone B cells of the spleen. The identification of a distinct precursor B-lineage cell population for murine B-1 cells in the fetal murine bone marrow [951] has confirmed that B-1 and B-2 are distinct cell lineages, but an analogous human B-1 committed precursor cell population has not yet been identified.

Murine naïve B-1 cells and marginal zone B cells are important contributors to the early and rapid production of IgM in response to blood-borne particulate antigens and to other T-independent antigens [952]. B-1 cells are commonly reactive with self-antigens, such as DNA, and foreign antigens, such as viral proteins or bacteria-derived products such as phosphorylcholine. In mice, B1a cells seem to be essential for the production of natural antibodies that provide protection against encapsulated bacteria, whereas B1b cells are essential for producing anticapsular antibodies in response to immunization [953].

A distinct feature of human fetal and neonatal B cells is the high frequency of CD5 expression compared with unfractionated circulating adult B cells. More than 40% of B cells in the fetal spleen, omentum, and circulation at mid-gestation are CD5+ [954–956]; CD5+ B cells also are present in the neonatal circulation [487] and gradually decline with postnatal age [954]. Fetal and newborn CD5+ B cells express IgM antibodies that are polyreactive, including reactivity with self-antigens, such as DNA [954,955,957], and this has been interpreted as the fetal and neonatal B-cell compartment being enriched for B-1 cells. More recent studies indicate, however, that the high level of CD5 expression by human fetal and cord blood B cells and the polyreactivity of their IgM are fully accounted for by a high frequency of new emigrant B cells in early ontogeny [869,870,958]. It is unclear whether the frequency, distribution, and function of B-1 cells differ in the human fetus and neonate compared with the adult; this requires the development of new markers that can distinguish human B-1 cells from B-2 cells.

In mice, B-1 cells constitute the major source of the low amounts of circulating "natural" IgM present at birth produced in the absence of antigenic stimulation, and animals lacking the ability to secrete natural IgM have an increased susceptibility to acute peritonitis from endogenous bacteria [959]. Although natural IgM antibodies are of low affinity, they can activate complement, which may allow antigenically naïve B cells to become activated as a result of receiving costimulation via CD21. In addition to a role in host defense, natural IgM may also play a role in removing apoptotic cells [847].

As discussed subsequently ("Immunoglobulin Synthesis by the Fetus and Neonate"), total circulating IgM is very low in the fetus and healthy newborn. Nevertheless, antigen microarrays have revealed that most cord blood sera have IgM that reacts with multiple self-antigens, such as single-stranded DNA, whereas such reactivity is lacking in maternal IgM [960]. Some autoreactivity was observed with cord blood IgA, although to a much lesser degree than for IgM. The importance of natural IgM in human host defense in the fetus and neonate and its B-cell source is unclear.

## T CELL–DEPENDENT AND T CELL–INDEPENDENT RESPONSES BY B CELLS

### Overview

The chronology of the response to various antigens differs, depending on the need for cognate T-cell help (Table 4–7). Largely on the basis of findings in murine studies, antigens

**TABLE 4–7** Hierarchy of Antibody Responsiveness

| Species | Type of Antigen | Examples of Antigen | Age at Onset of Antibody Response |
|---|---|---|---|
| Mouse | T cell–dependent | TNP-KLH | Birth |
| | T cell–independent type I | TNP–*Brucella abortus* | Birth |
| | T cell–independent type II | TNP-Ficoll | Delayed (2-3 wk of age) |
| Human | T cell–dependent | Tetanus toxoid, HBsAg, *Haemophilus influenzae* conjugate vaccine, bacteriophage φX174 | Birth |
| | T cell–independent type I | TNP–*B. abortus* | Birth |
| | T cell–independent type II | Bacterial capsular polysaccharides (*H. influenzae* type b, *Neisseria meningitidis*, *Streptococcus pneumoniae*, GBS) | Delayed (6-24 mo of age) |

*GBS, group B streptococci, HBsAg, hepatitis B surface antigen; KLH, keyhole limpet hemocyanin; TNP, trinitrophenol.*

*Adapted from Stiehm ER, Fudenberg HH. Serum levels of immune globulins in health and disease: a survey. Pediatrics 37:715, 1966.*

can be divided into antigens dependent on a functional thymus and cognate help (direct cell-cell interactions) provided by mature αβ T cells (T-dependent antigens) and antigens partially or completely independent of T-cell help (T-independent antigens). T-independent antigens can be divided further into T-independent type I and T-independent type II, in accordance with their dependence on cytokines produced by T cells (or other cells).

Most proteins are T-dependent antigens requiring cognate T-cell–B-cell interaction for production of antibodies (other than small amounts of IgM). The antibody response to T-dependent antigens is characterized by the generation of memory B cells with somatically mutated, high-affinity immunoglobulin and the potential for isotype switching.

T-independent type I antigens are antigens that bind to B cells and directly activate them in vitro to produce antibody without T cells or exogenous cytokines. In the human, one such T-independent type I antigen is fixed *Brucella abortus*. T-independent type II antigens are mostly polysaccharides with multiple identical subunits and certain proteins that contain multiple determinants of identical or similar antigenic specificity. Responses to these antigens are enhanced in vitro and in vivo by cytokines, including IL-6, IL-12, IFN-γ, and GM-CSF [961–964]. NK cells, T cells, NKT cells, macrophages, and DCs may provide these cytokines. T-independent type II responses also are enhanced by bacterially derived TLR ligands, including LPS, lipoproteins, and unmethylated CpG DNA [963,965–967].

The response to T-independent type II antigens is characterized by the lack of B-cell memory and is restricted largely to the IgM and $IgG_2$ isotypes [883]. The IgM response to T-independent type II antigens seems to be mediated mainly by $IgM^+IgD^+CD27^+$ B cells, which have a high degree of somatic hypermutation of their immunoglobulin genes that seems to be generated before their encountering antigen. Immunization with T-independent type II antigens may result in the appearance of additional somatic hypermutations of the antibody produced by $IgM^+IgD^+CD27^+$ B cells [968], although whether this represents the expansion of previously mutated clones that were undetectable before immunization versus additional somatic hypermutations is unclear. Such additional antigen-induced somatic hypermutation is a controversial mechanism because most studies have found that $IgM^+IgD^+CD27^+$ B cells of the spleen and circulation have undetectable levels of the AID enzyme, which is absolutely required for somatic hypermutation.

## Response to T Cell–Dependent Antigens

The capacity of the neonate to respond to T-dependent antigens is well established at birth (see Table 4–7) and is only modestly reduced compared with the response in the adult. Several mechanisms, alone or in combination, may be responsible for this modest reduction, including decreased DC interactions or function with CD4 T cells or B cells, limitations in CD4 T-cell activation and expansion into a T helper/effector cell population, impaired cognate interactions between CD4 T cells and B cells, or an intrinsic B-cell defect. Another possibility is that T-dependent antigens preferentially upregulate CD22, which raises the threshold for B-cell activation, on neonatal compared with adult B cells [884]. Because neonatal B cells are highly enriched for the new emigrant subset, it is plausible that this subset may be less effective at responding to T-dependent antigens than fully mature naïve B cells, which predominate in the non–memory B-cell compartment of adults.

Most studies of the neonatal immune response to T-dependent antigens have not evaluated antibody affinity, a reflection of somatic mutation, or isotype expression. Such responses, particularly isotype switching, might be limited early in the immune response because of decreased CD40 ligand expression by CD4 T cells [608,611,969]. Studies are needed to determine if reductions in CD40 ligand expression by antigen-specific T cells also occur in response to neonatal vaccination and, if so, whether such reduced expression correlates with reduced memory B-cell development, decreased isotype switching, and somatic hypermutation. An additional factor that may contribute to the modest reduction in T-dependent antibody production is the reduced expression on B cells (nearly all of which are naïve $IgM^+IgD^+CD27^+$ follicular B cells) from preterm and, to a lesser degree, term neonates of receptors for BAFF and APRIL, which help promote T-dependent differentiation into plasma cells and plasma cell survival [950].

## Response to T Cell–Independent Antigens

Antibody production by human neonatal B cells to a T-independent type I antigen in vitro (*B. abortus*) is only modestly reduced (see Table 4–7) [970]. This reduction may reflect a decreased ability of antigen-activated B cells to proliferate, rather than a decreased precursor frequency of antigen-specific clones [970].

In humans and mice, the response to T-independent type II antigens is the last to appear chronologically (see Table 4–7). This helps to account for the neonate's susceptibility to infection with encapsulated bacteria, such as GBS, and the poor response to polysaccharide antigens from other capsulated bacterial pathogens until approximately 2 to 3 years of age. The poor response in neonates is associated with their relatively low levels of circulating $IgM^+IgD^+CD27^+$ B cells, which are characteristically found in the marginal zone of the spleen and other extrafollicular sites, such as the tonsils. More recent studies have documented these cells in the marginal zone region of the spleen and blood in substantial numbers during the first 2 years of life, however, arguing that the poor response to T-independent type II antigens is not simply a quantitative defect of this B-cell subset. Rather, the decreased responses to T-independent type II antigens during early childhood probably reflect an intrinsic immaturity of $IgM^+IgD^+CD27^+$ B cells, perhaps including decreased expression of BAFF and APRIL receptors [950] or decreased function of other cell types that support their differentiation and function.

Decreased expression of CD21 on neonatal B cells has been proposed as a possible mechanism for limitations in T-independent type II response in the neonate

[971,972]. CD19 is expressed in association with CD21, the type 2 complement receptor, and serves to transduce B cell–activating signals when CD21 is engaged by C3 complement components [892], inducing polysaccharide-reactive B cells to proliferate in vivo. Genetic disruption experiments in mice support the idea that the type 2 complement receptor, which includes CD21 and CD35 in mice, is important for T-independent type II antibody responses to pathogens, such as *S. pneumoniae* [944]. In vitro studies of human splenic tissue suggest that T-independent type II antigens activate complement and bind C3 and then localize to the marginal zone splenic B cells expressing complement receptors [883]. Whether IgM$^+$IgD$^+$CD27$^+$ B cells of the neonate and young infant have reduced CD21 expression compared with B cells of older children and adults is unclear, however.

Human neonatal B cells show a marked decrease in CD22 expression after engagement of IgM, a stimulus used to mimic a T-independent type II antigen [884]. Because CD22 is a negative regulator of B-cell activation, however, this finding does not explain the diminished response, unless it results in hyperresponsive neonatal B cells prone to apoptosis.

Dextran-conjugated anti-immunoglobulin mAbs have been used to mimic the events in T-independent type II antibody responses in vitro [963]. Human neonatal B cells respond to this stimulus as well as adult B cells, suggesting that the lack of the neonatal T-independent type II response is not due to an intrinsic limitation in their activation via surface immunoglobulin cross-linking [973]. B cells that respond to dextran-conjugated anti-immunoglobulin mAbs may be enriched for B cell types, such as new emigrant B cells and fully mature naïve B cells, that are functionally distinct, however, from IgM$^+$IgD$^+$CD27$^+$ B cells that respond to polysaccharides or other T-independent type II antigens.

The response of human cord blood and adult peripheral blood B cells to CpG oligonucleotides is similar in terms of cell proliferation, the production of chemokines (CCL3 [MIP-1α] and CCL4 [MIP-1β]), and upregulation of CD86 and MHC class II expression [881]. This indicates that neonatal B-cell expression of TLR9 is similar to that of the adult, and the TLR9 signaling pathway, which involves MyD88, is intact. These findings are consistent with a more recent study [968] showing that new emigrant B cells of the adult and neonate express high levels of TLR9 and are capable of secreting IgM and IgG after stimulation with CpG oligonucleotides in the absence of added exogenous cytokines, including detectable levels of antipneumococcal polysaccharide IgM antibody. This stimulus also increases new emigrant B-cell expression of AID and BLIMP-1, consistent with the acquisition of the ability to secrete isotype-switched IgG plasma cells and the acquisition of a plasmablast surface phenotype by a substantial cell fraction [968].

Some of these CpG oligonucleotide–stimulated new emigrant B cells of the neonate acquire a CD27$^+$IgM$^+$ surface phenotype reminiscent of the IgM$^+$IgD$^+$CD27$^+$ B-cell subset of the marginal zone of the spleen and circulation [968] (see "Marginal Zone B Cells of the Spleen and IgM$^+$IgD$^+$CD27$^+$ B Cells" earlier). These observations raise the possibility that new emigrant B cells in the neonate and young infant may give rise to the IgM$^+$IgD$^+$CD27$^+$ B-cell subset implicated in the IgM response to T-independent type II antigens and that this maturation may be enhanced by exposure to bacterial-derived products, such as CpG-containing DNA, in an antigen-independent manner.

A striking feature of the IgM$^+$IgD$^+$CD27$^+$ B-cell subset is its high degree of preimmune somatic hypermutation of the immunoglobulin genes; an analysis of the immunoglobulin repertoire of IgM$^+$IgD$^+$CD27$^+$ B cells generated from adult or cord blood new emigrant B cells would be of interest in future studies. This hypothesized postnatal pathway for IgM$^+$IgD$^+$CD27$^+$ B-cell maturation is distinct from a pathway that is operative in the fetus in which these somatically hypermutated preimmune IgM$^+$ B cells are generated in a sterile environment [948]. Finally, the TLR9 pathway also is capable of inducing naïve adult B cells to produce IL-12p70, a key cytokine for promoting $T_H1$ differentiation as discussed earlier, but it is unknown whether neonatal B cells are also capable of IL-12p70 production under these conditions.

## SPECIFIC ANTIBODY RESPONSE BY THE FETUS TO MATERNAL IMMUNIZATION AND CONGENITAL INFECTION

### Response to Fetal Immunization in Animal Models

Early studies by Silverstein and colleagues [974] of the antibody response of fetal sheep and rhesus monkeys to immunization with foreign proteins were conceptually important in establishing two major features of the ontogeny of B-cell immune competence for T cell–dependent antigens in larger mammals. First, immune competence for T cell–dependent antigens is established early during fetal ontogeny: Primary immunization of fetal rhesus monkeys between 103 and 127 days of gestation (out of a total of 160 days) with sheep red blood cells, a T cell–dependent antigen, results in the formation of sheep red blood cell–reactive B cells in the spleen; reimmunization 3 weeks later results in a rapid antibody response using IgG. In fetal sheep, the antibody response to bacteriophage φX174 occurs 40 days after conception [975], and isotype switching is evident during the fetal response.

Together, these findings suggest that the B-cell responses to protein antigens, including isotype switching and probably memory cell generation, are functional during fetal life. Second, these responses occur in a predictable, stepwise fashion for particular antigens. In fetal sheep, the antibody responses to keyhole limpet hemocyanin and lymphocytic choriomeningitis virus are first detectable at about 80 and 120 days after conception [975]. These differences in the responsiveness to particular antigens are not explained by limitations in the repertoires of surface immunoglobulin or αβ-TCRs.

No correlation exists between the physical or chemical characteristics of particular antigens and their immunogenicity during ontogeny. Bacteriophage φX174 and

bacteriophage T4 are particulate antigens that should interact in a similar manner. In fetal sheep, however, bacteriophage T4 becomes immunogenic 60 days after φX174 does so. Baboon fetuses immunized with HBsAg vaccine have a robust IgG antibody response, and this response is boosted by postnatal immunization [976].

### Response to Maternal Immunization

In studies by one group of investigators, antibody responses by the human fetus may occur after maternal immunization with tetanus toxoid during the third trimester but not earlier, as shown by the presence of IgM tetanus antibodies at birth [977,978]. Whether tetanus-specific IgG responses at birth were reduced, as suggested by reports of reduced CD4 T-cell responses to tetanus vaccine in young infants [812], is unclear. Infants with tetanus-specific antibodies at birth had enhanced secondary antibody responses after tetanus immunization, indicating that fetal antigen exposure was a priming event, rather than a tolerizing one [977]. Englund and associates [785] were unable to show neonatal tetanus toxoid–specific IgM antibody or T-cell proliferation after maternal tetanus toxoid vaccination in the third trimester. Similarly, no fetal response to maternal immunization with inactivated trivalent influenza vaccine was noted [785]. Another study found, however, that maternal immunization with a split influenza vaccine during the second and third trimesters of pregnancy resulted in detectable IgM-specific responses to influenza proteins in cord blood [784]. If adequate fetal antibody responses to maternal vaccination with polysaccharide-protein conjugate vaccines occurred, such vaccines could be used during pregnancy to ensure that protective antibody levels were present at birth.

### Response to Intrauterine Infection

Specific antibody may be present at birth to agents of intrauterine infection, including rubella virus, CMV, HSV, VZV, and *T. gondii*, and often can be used to diagnose congenital infection. Not all fetuses have an antibody response to intrauterine infection, however; specific IgM antibody was undetectable in 34% of infants with congenital rubella [979], 19% to 33% of infants with congenital *T. gondii* infection [980,981], and 11% of infants with congenital CMV infection [982]. When congenital infection is severe during the first or second trimester, antibody production may be delayed until late childhood [799]. This delay may reflect a lack of T-cell help because antigen-specific T-cell responses often are reduced in parallel with B-cell responses.

Congenital *T. gondii* infection may lead to detectable IgE and IgA anti–*T. gondii* antibodies at birth or during early infancy [983]. Similarly, filaria-specific or schistosome-specific IgE is present in the sera of most newborns after maternal filiariasis or schistosomiasis [984]. T cell–dependent isotype switching and immunoglobulin production occur during fetal life, at least for certain pathogens. With some infectious agents, such as *T. gondii*, IgA or IgE antibodies may be more sensitive than IgM antibodies for diagnosis of congenital infection. The titers of IgA and IgE anti–*T. gondii* antibodies may be lower at 20 to 30 weeks of gestation than after birth [985–987], however, indicating that their production is delayed in the context of congenital infection.

## POSTNATAL SPECIFIC ANTIBODY RESPONSES

### Specific Antibody Responses by the Neonate and Young Infant to Protein Antigens

Immunization of neonates usually elicits or at least primes for a protective response to protein antigens, including tetanus and diphtheria toxoids [988], OPV [989], *Salmonella* flagellar antigen [990,991], bacteriophage φX174 [992], and HBsAg (with hepatitis B vaccine) [993]. The response to some vaccines may be less vigorous in the neonate, however, than in older children or adults. A diminished primary response to recombinant hepatitis B vaccine has been noted in term neonates lacking maternally derived HBsAg antibody compared with the response in unimmunized children and adults [993,994]. The ultimate anti-HBsAg titers achieved in neonates after secondary and tertiary immunizations are similar to titers in older children, indicating that neonatal immunization does not result in tolerance [993]. If initial immunization is delayed until 1 month of age, the antibody response to primary hepatitis B vaccination is increased and nearly equivalent to that in older children, suggesting that the developmental limitations responsible for reduced antibody responses are transient [993,995]. Similarly, 2-week-old infants immunized with a single dose of diphtheria or tetanus toxoid showed delayed production of specific antibody compared with older infants, but by 2 months of age, their response was similar to the response of 6-month-old infants [996]. The switch from IgM to IgG also may be delayed after neonatal vaccination for some (e.g., *Salmonella* H vaccine) [991], but not all (e.g., bacteriophage φX174) [992], antigens. Immunization of infants born to HIV-infected mothers with recombinant HIV-1 gp120 vaccine in MF59 adjuvant, beginning at birth, also resulted in high antibody titers, indicating that early postnatal vaccination is not tolerigenic [997].

In contrast to other vaccines, in newborns given whole-cell pertussis vaccination, not only may they show a poor initial antibody response, but also their subsequent antibody response to certain antigenic components, such as pertussis toxin, may be less than in infants initially immunized at 1 month of age or older [998–1000], suggesting low-level tolerance. Whole-cell pertussis vaccine immunization of premature infants (born at 28 to 36 weeks of gestation) at 2 months of age elicited responses similar to those in 2-month-old term infants [989], indicating that this putative tolerigenic period wanes rapidly and is relatively independent of gestational age. This low-level tolerance was restricted to the pertussis component of the whole-cell pertussis vaccine because an inhibitory effect has not been observed after administration of diphtheria or tetanus toxoid [988] or hepatitis B vaccine given within 48 hours of birth [993].

A more recent study [1001] also found that neonatal immunization with acellular pertussis vaccine combined with diphtheria and tetanus toxoids resulted in lower

subsequent pertussis-specific antibody responses than when vaccination was delayed. In contrast, and for unclear reasons, no such inhibition of pertussis-specific antibody responses was observed when the acellular pertussis vaccine was administered alone shortly after birth [1002,1003]. Administration of OPV at birth enhanced rather than inhibited the response to subsequent immunization, also indicating that immunization through the mucosal route does not produce tolerance [1004].

The antibody response to measles vaccine given at 6 months of age is significantly less than when the vaccine is given at 9 or 12 months of age, even when the inhibitory effect of maternal antibody is controlled for [1005]. This decreased response is not due to a lack of measles-specific T cells because measles antigen–specific T-cell proliferation and IL-12 and IFN-$\gamma$ proliferation were similar in the three age groups [1005–1007]. Although the basis for this reduced response is unknown, early vaccination in infants 6 months of age does not impair the antibody and T-cell response after a second dose of vaccine at 12 months [1008]. Thus, there is no evidence for a tolerigenic effect from early measles vaccination.

## Specific Antibody Responses by the Term Neonate to Polysaccharide and Polysaccharide-Protein Conjugates

In contrast to the response to protein antigens, the newborn's response to polysaccharide antigens is absent or severely blunted, as shown by an inability to mount an antibody response to unconjugated *H. influenzae* type b (Hib) polysaccharide vaccine or to group B streptococcal capsular antigens after infection. The response to some polysaccharide antigens can be shown by 6 months of age, but the response to vaccination with Hib, most pneumococcal serotype polysaccharides, and *N. meningitidis* type C is poor until 18 to 24 months of age [1009]. The delayed postnatal appearance of marginal zone B cells in the spleen has been proposed to account for this delayed response (see "Development of B-Cell Capacity to Respond to T-Cell–Dependent and T-Cell–Independent Antigens"), although this suggestion is controversial, as noted in the preceding sections.

Covalent conjugation of Hib capsular polysaccharide to a protein carrier renders it immunogenic in infants 2 months of age and primes for an enhanced antibody response to unconjugated vaccine given at 12 months of age. Because the response to the unconjugated vaccine usually is poor at this age, the conjugate vaccine acts by inducing Hib polysaccharide–specific B-cell memory [1010]. Similarly, the administration of a single dose of Hib polysaccharide–tetanus toxoid conjugate to term neonates at a few days of age may enhance the antibody response to unconjugated Hib polysaccharide vaccine at 4 months [1011]. This enhanced response is weak, however, and does not occur when the neonate is primed with tetanus toxoid followed by immunization with conjugate vaccine at 2 months of age [1012]. Although administration of a single dose of Hib polysaccharide–meningococcal outer membrane protein complex conjugate at 2 months of age is highly immunogenic, administration to term neonates induces persistent unresponsiveness to subsequent immunizations throughout the first year of life [1013,1014]; the basis for this unresponsiveness is unknown.

Coupling of the Hib polysaccharide to a protein carrier converts a T-independent type II antigen to a T-dependent antigen [1015]. This change is accompanied by an enhanced magnitude and higher avidity antibody response on subsequent boosting, presumably resulting from T-dependent memory B-cell generation and somatic hypermutation. The early interactions between T cells and B cells in response to such carbohydrate-protein conjugate vaccines are summarized in Figure 4–15. Conjugation of Hib polysaccharide to tetanus or diphtheria toxoid does not change the repertoire of the antibodies produced from that of the free polysaccharide [1010,1016]. Vaccination with protein–capsular polysaccharide conjugate vaccines containing polysaccharides of *S. pneumoniae* (types 4, 6B, 9V, 14, 18C, 19F, and 23F in the Danish nomenclature) [1017] and *N. meningitidis* (types A and C) [1018] is immunogenic in infants 2 months of age and primes them for subsequent memory responses.

## Antibody Responses by the Premature Infant to Immunization

Preterm neonates of 24 weeks of gestation or greater produce antibody to protein antigens such as diphtheria toxoid, diphtheria-pertussis-tetanus vaccine, and oral and inactivated poliovirus vaccines as well as term neonates when the vaccines are administered at 2, 4, and 6 months of age [989,1019–1022]. The antibody response in

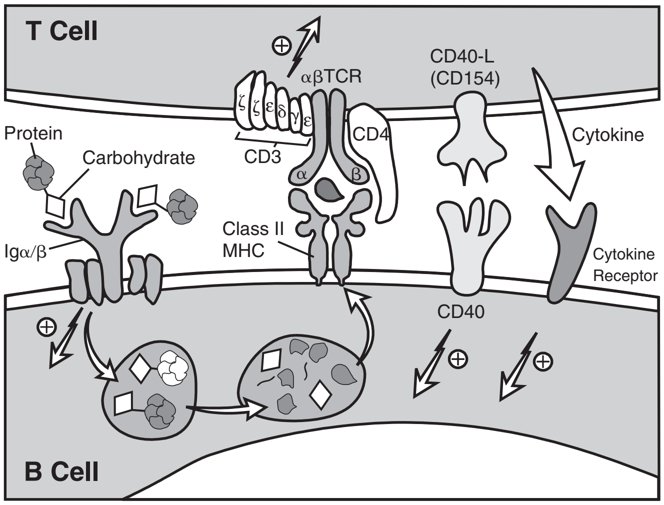

**FIGURE 4–15 Interactions between B cells and T cells in response to vaccines consisting of purified carbohydrate (e.g., bacterial capsular polysaccharide) covalently linked to protein carrier.** The carbohydrate moiety of the conjugate is bound by surface immunoglobulin on B cells, resulting in internalization of the conjugate. Peptides derived from the protein moiety of the conjugate are presented by major histocompatibility complex (MHC) class II on the B cell resulting in the activation of the T cell and expression of CD40 ligand. Engagement of CD40 on the B cell by CD40 ligand, in conjunction with cytokines secreted by the T cell, results in carbohydrate-specific B-cell proliferation, immunoglobulin isotype switching, secretion of antibody, and memory B-cell generation.

premature infants to multiple doses of hepatitis B vaccine, initially administered at birth, is reduced compared with term infants [1023,1024]. These titers are substantially increased if immunization of the premature infant is delayed until 5 weeks of age, indicating the importance of postnatal age over a particular body weight [1025]. The benefits of such a delay for long-term hepatitis B–specific antibody levels persist for at least the first 3 years of life [1026].

The antibody levels after three doses of Hib polysaccharide–tetanus conjugate vaccine are significantly less in premature infants than in term infants when vaccination is begun at 2 months of age [1027,1028]. This reduced antibody response occurs particularly in premature infants with chronic lung disease [1029], in whom it may result in part from glucocorticoid treatment.

## MATERNALLY DERIVED IgG ANTIBODY

The transfer of IgG to the fetus depends on the recognition of maternal IgG through its Fc domain. IgG is internalized by the syncytiotrophoblast, possibly by pinocytosis, and binds to FcRn (also known as the Brambell receptor, FcRB) in the early endosome [1030]. FcRn is a unique $\beta_2$-microglobulin–associated nonpolymorphic member of the MHC class I family, which lacks a functional peptide-binding groove and instead uses a different region of the molecule to bind the Fc domain of IgG [1031]. IgG bound to FcRn undergoes transcytosis across the syncytiotrophoblast and is released into the fetal circulation. In addition to the syncytiotrophoblast, FcRn is widely expressed by nonplacental tissues, where it binds to pinocytosed IgG and recycles it to the circulation [1030]. This recycling system accounts for the very long half-life of IgG.

Maternal IgG and FcRn expression can be detected in placental syncytiotrophoblasts during the first trimester [1032], but transport does not occur until about 17 weeks of gestation. The maternally derived placental cytotrophoblast, which is found between the syncytiotrophoblast and the fetal endothelium during the first trimester, may act as a barrier to IgG transport. This cytotrophoblast layer becomes discontinuous as the villous surface area expands during the second trimester [1032].

IgG is detectable in the fetus by 17 weeks of gestation, after which circulating concentrations increase steadily, reaching half of the term concentration by about 30 weeks and equaling that of the mother by about 38 weeks [1033,1034]. In some instances, fetal IgG concentrations may exceed IgG concentrations of the mother [1035,1036].

The fetus synthesizes little IgG—the concentration in utero is almost solely maternally derived (Fig. 4–16) [1037]. Accordingly, the degree of prematurity is reflected in proportionately lower neonatal IgG concentrations. The $IgG_2$ concentration in cord blood relative to the

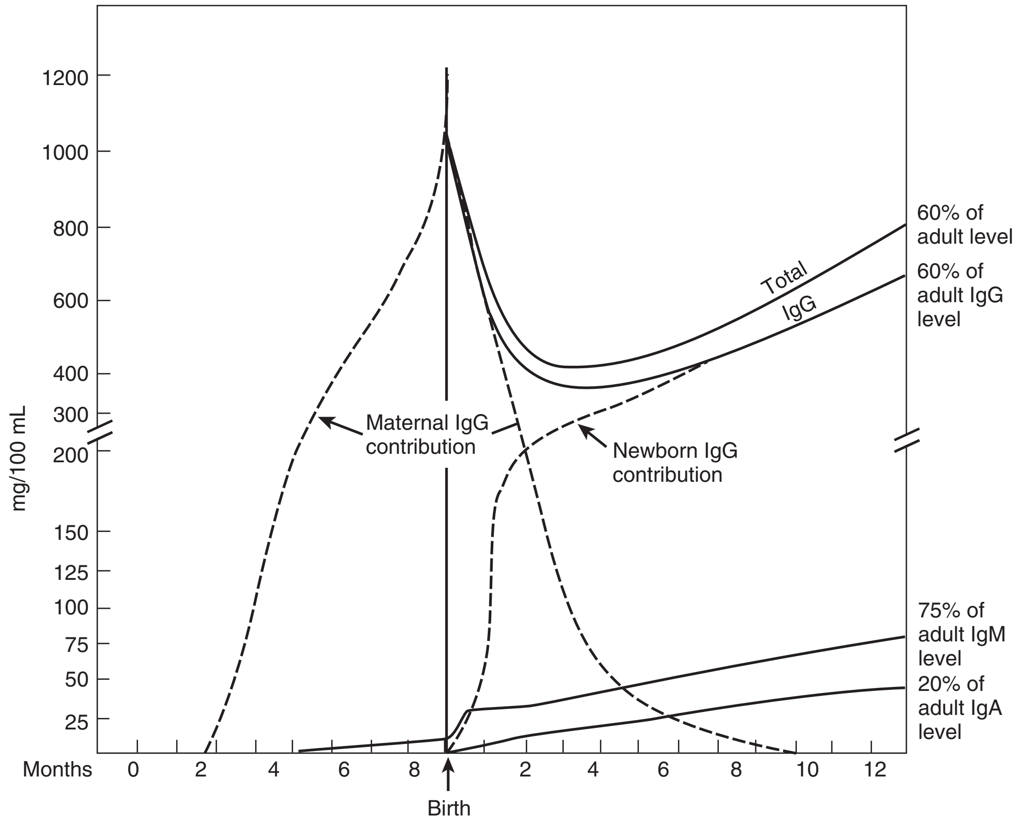

**FIGURE 4–16 Immunoglobulin (IgG, IgM, and IgA) levels in the fetus and in the infant in the first year of life.** IgG of the fetus and newborn infant is solely of maternal origin. Maternal IgG disappears by age 9 months, by which time endogenous synthesis of IgG by the infant is well established. IgM and IgA of the neonate are entirely endogenously synthesized because maternal IgM and IgA do not cross the placenta. *(Data from Saxon A, Stiehm ER. The B-lymphocyte system.* In *Stiehm ER [ed]. Immunologic Disorders in Infants and Children, 3rd ed. Philadelphia, WB Saunders, 1989, pp 40-67.)*

concentration in maternal blood is low at birth, particularly in preterm infants, whereas the overall fetal-to-maternal ratio is usually near 1.0 for the other IgG subclasses [1038–1040]. The low $IgG_2$ concentration seems to reflect a relatively low affinity of FcRn for $IgG_2$. IgM, IgA, IgD, and IgE do not cross the placenta. Evidence for transamniotic transfer of IgG to the fetus also is lacking [1036].

## Placental Transfer of Specific Antibodies

The fetus receives IgG antibodies against antigens to which the mother has been exposed by infection or vaccination. In mothers immunized with Hib capsular polysaccharide antigen at 34 to 36 weeks of gestation, concentrations of anticapsular antibody are high, resulting in protective antibody levels in infants for approximately the first 4 months of life. In the absence of recent immunization or natural exposure, the maternal antibody IgG antibody titer may be too low to protect the neonate. Protection of the infant may be absent even if the mother is protected because she has memory B cells and can mount a rapid recall antibody response on infectious challenge. In addition, if maternal antibodies are primarily IgM, such as antibodies to *E. coli* and *Salmonella* [990,991], the fetus would not be protected because IgM does not traverse the placenta. Finally, premature infants may not receive sufficient amounts of IgG for protection because the bulk of maternal IgG is transferred to the fetus after 34 weeks of gestation [1041], accounting for the greater susceptibility of premature neonates compared with term neonates to certain infections, such as with VZV [1042].

## Inhibition of Neonatal Antibody Responses by Maternal Antibodies

Maternal antibody also may inhibit the production by the fetus or newborn of antibodies of the same specificity. This inhibition varies with the maternal antibody titer and with the type and amount of antigen. Maternal antibody markedly inhibits the response to measles and rubella vaccine, but not mumps vaccine [1043]; this is the reason for delaying measles-mumps-rubella (MMR) vaccine until at least 12 months of age in the developed world. Inhibition of the response to these live-attenuated viral vaccines may result in part from the binding of maternal antibody to immunogenic epitopes, inhibiting antigen binding to surface immunoglobulin on the antigen-specific B cells of the infant (i.e., masking), and from reduced replication of vaccine virus.

Maternal antibodies also may inhibit the response of the neonate and young infant to certain nonreplicating vaccines, such as whole-cell pertussis vaccine [1000], diphtheria toxoid [1044], *Salmonella* flagellar antigen [991], and inactivated poliovirus vaccine [1045], but not others, such as Hib conjugate vaccine [1046]. Maternal antibody may mask the immunogenic epitope, and formation of maternal IgG antibody–antigen complexes may inhibit activation of B cells via surface immunoglobulin by simultaneous engagement of the inhibitory FcγRII receptor by the IgG component of the complex [120]. Alternatively, maternal antibody may lead to the rapid clearance of vaccine antigen and decreased immunogenicity. Maternal antibodies may enhance, rather than inhibit, the T-cell response to postnatal vaccination, as in the case of tetanus toxoid [1047]. Finally, for certain antibodies, such as anti-HbsAg, neither maternal antibodies nor hepatitis B immune globulin administration has a substantial inhibitory effect on the newborn's immune response to hepatitis B vaccination.

# IMMUNOGLOBULIN SYNTHESIS BY THE FETUS AND NEONATE

## IgG

IgG is the predominant immunoglobulin isotype at all ages (Table 4–8) [1048]. In adults, IgG1 is the predominant subclass, accounting for approximately 70% of total IgG; IgG2, IgG3, and IgG4 account for approximately 20%, 7%, and 3% of the total [1049]. Passively derived maternal IgG is the source of virtually all of the IgG subclasses detected in the fetus and neonate. Because the IgG

plasma half-life is about 21 days, these maternally derived levels decline rapidly after birth. IgG synthesized by the neonate and IgG derived from the mother are approximately equal at 2 months of age, and by 10 to 12 months of age, the IgG is nearly all derived from synthesis by the infant. As a consequence of the decline in passively derived IgG and increased synthesis of IgG, values reach a nadir of approximately 400 mg/dL in term infants at 3 to 4 months of age and increase thereafter (see Table 4–8 and Fig. 4–16). The premature infant has lower IgG concentrations at birth, which reach a nadir at 3 months of age; mean IgG values of 82 mg/dL and 104 mg/dL are observed in infants born at 25 to 28 weeks of gestation and 29 to 32 weeks of gestation.

By 1 year, the total IgG concentration is approximately 60% of that in adults. IgG3 and IgG1 subclasses reach adult concentrations by 8 years, whereas IgG2 and IgG4 reach adult concentrations by 10 and 12 years of age [1050]. As discussed earlier, maternal IgG may inhibit certain postnatal antibody responses by binding to FcγRII receptors and by rapidly clearing or masking potential antigens. The slow onset of IgG synthesis in the neonate is predominantly an intrinsic limitation of the neonate, however, rather than of maternal antibody; a similar pattern of IgG development was observed in a neonate born to a mother with untreated agammaglobulinemia [1051].

The slow increase in IgG2 concentrations parallels the poor antibody response to bacterial polysaccharide antigens, which are predominantly IgG2 [1052]. The postpartum order in which adult levels of isotype expression are achieved closely parallels the chromosomal order of the heavy chain gene segments that encode these isotypes. Postnatal regulation of isotype switching is mediated partly at the heavy chain gene locus. Although passive maternal antibody plays an important role in protection, it limits the value of immunoglobulin and antibody levels in the diagnosis of immunodeficiency or infection in the young infant.

## IgM

IgM is the only isotype besides IgG that binds and activates complement. IgM has a half-life in the blood of 5 days. The concentration of IgM in the blood increases from a mean of 6 mg/dL in infants born at less than 28 weeks of gestation to 11 mg/dL in infants born at term [1053,1054], which is approximately 8% of the maternal IgM level. This IgM, which is likely to be preimmune (i.e., not the result of a B-cell response to foreign antigens), is enriched for polyreactive antibodies. Murine studies suggest that such natural IgM plays an important role in innate defense against infection, allowing time for the initiation of antigen-specific B-cell response; it also enhances antigen-specific B-cell responses through its ability to fix complement and costimulate B-cell activation through CD21 [892]. Some human neonatal IgM is monomeric and nonfunctional, however, as opposed to its usual pentameric functional form [1055,1056].

Postnatal IgM concentrations increase rapidly for the first month and then more gradually thereafter, presumably in response to antigenic stimulation (see Fig. 4–16 and Table 4–8). By 1 year of age, values are approximately 60% of those in adults. The postnatal increase is similar in premature and in term infants [1055]. Elevated (>20 mg/dL) IgM concentrations in cord blood suggest possible intrauterine infections [1057], but many infants with congenital infections have normal cord blood IgM levels [982].

## IgA

IgA does not cross the placenta, and its concentration in cord blood usually is 0.1 to 5 mg/dL, approximately 0.5% of the levels in maternal sera [1054]. Concentrations are similar in term and in premature neonates [1053], and IgA1 and IgA2 are present. IgA has a half-life in the blood of 6 days.

At birth, the frequency of IgA1-bearing and IgA2-bearing B cells is equivalent. Subsequently, a preferential expansion of the IgA1-bearing cell population occurs [1058]. Concentrations in serum increase to 20% of those in adults by 1 year of age and increase progressively through adolescence (see Table 4–8). Increased cord blood IgA concentrations are observed in some infants with congenital infection [1057] and is common in infants infected with HIV by vertical transmission. Secretory IgA is present in substantial amounts in the saliva by 10 days after birth [1059].

## IgD

IgD is detectable by sensitive techniques in serum from cord blood in term and premature infants [1053,1060]. Mean serum levels at birth are approximately 0.05 mg/dL [1054] and increase during the first year of life [1061]. IgD is also detectable in the saliva of newborn infants [1059]. Circulating or salivary IgD have no clear functional role because mice in which IgD expression has been eliminated by gene targeting seem to be normal. Surface IgD can replace surface IgM in B-cell function in the mouse.

## IgE

Although IgE synthesis by the fetus is detectable at 11 weeks, concentrations of IgE in cord blood are typically low, with a mean of approximately 0.5% of that of maternal levels [1054]. This IgE is of fetal origin, and concentrations are higher in infants born at 40 to 42 weeks of gestation than in infants born at 37 to 39 weeks [1054]. The rate of postnatal increase varies and is greater in infants predisposed to allergic disease or greater environmental exposure to allergens [1062,1063]. The concentration of IgE at birth seems to have limited predictive value for later development of atopic disease for most individuals [1063,1064].

# SUMMARY

The neonate is partially protected from infection by passive maternal IgG antibody, predominantly transferred during the latter third of pregnancy. Fetal IgG concentrations are equal to or higher than maternal concentrations at term. The inability of the neonate to produce antibodies in response to polysaccharides, particularly bacterial capsular polysaccharides, limits resistance to bacterial pathogens to

which the mother has little or no IgG antibody. The basis for this defect is unclear, but it may reflect an intrinsic limitation of B-cell function or a deficiency in the anatomic microenvironment required for B cells to become activated and differentiate into plasma cells. By contrast, the neonatal IgM response to most protein antigens is intact and only slightly limited for IgG responses to certain vaccines.

A clear difference between neonates and older infants has been observed in the magnitude of the antibody response to most protein neoantigens, but this difference rapidly resolves after birth. The predominance of transitional B cells in the fetus and neonate may account in part for limitations in function. A limited antibody response of premature infants to immunization with protein antigens occurs during the first month of life, but not subsequently. Chronologic (i.e., postnatal) age is a more important determinant of antibody responses to T-dependent antigens than gestational age. Isotype expression by B cells after immunization with T-dependent antigens is limited by altered T-cell function, such as reduced CD40 ligand production, and intrinsic limitations of B-cell maturation and function. These limitations are exaggerated in the fetus.

# HOST DEFENSE AGAINST SPECIFIC CLASSES OF NEONATAL PATHOGENS

## EXTRACELLULAR MICROBIAL PATHOGENS: GROUP B STREPTOCOCCI

### Overview of Host Defense Mechanisms

Infection of the neonate with GBS in most cases results from aspiration of infected amniotic or vaginal fluid, followed by adherence to and subsequent invasion through the respiratory mucosa. Initial colonization is influenced by the organism's ability to adhere to mucosal epithelial cells. Physical disruption of the mucosal epithelium may not be required for tissue invasion because GBS can enter into the cytoplasm of cultured respiratory epithelial cells by an actin microfilament–dependent process [202]. Specific secretory IgA antibody and fibronectin may decrease bacterial adherence to the mucosa. As noted in "Antimicrobial Peptides," epithelial cells in the skin, tongue, and airways express β-defensins and the cathelicidin LL-27, which are active against GBS [1–4].

When GBS cross the mucosal epithelium and enter the tissues, phagocytes and opsonins become the critical elements of defense. Antibody and complement opsonize the bacteria for phagocytosis and killing by neutrophils and macrophages, but similar to all gram-positive bacteria, these organisms are resistant to lysis by complement. GBS and strains of *E. coli* that cause serious neonatal infections possess type-specific polysaccharide capsules, which impede or block antibody-independent activation of the alternative and MBL complement pathways [54,60,1065]. Consistent with this notion, there is an inverse correlation between the degree of encapsulation and the deposition of C3b on type III GBS through the alternative pathway [1066], although some studies have not found an effect of capsule on complement deposition [1067].

Efficient complement activation leading to deposition of C3b and C3bi on the bacterial surface depends on type-specific anticapsular IgG antibody [1068]. Consistent with these findings, susceptibility to infection with type III GBS is essentially limited to infants lacking type-specific antibody (see Chapter 12). Complement also plays an important role. In animal models, complement components C3 and C4 are required for protection before the development of type-specific antibodies, suggesting that antibody-independent activation of the C4 complement component by the MBL pathway may be involved, whereas C3, but not C4, is required when type-specific antibodies are produced [1069]. IgG-coated and, in the lung, surfactant apoprotein A–coated bacteria are ingested by phagocytes, and ingestion is augmented by C3b and C3bi.

Small numbers of GBS may be cleared by resident lung macrophages [202]. If the bacteria are not cleared, neutrophils and monocytes are recruited to the site of infection by chemotactic factors, including fMLP, C5a, $LTB_4$, and chemokines (e.g., CXCL8) [1070]. Many strains of GBS contain an enzyme, C5a-ase, which degrades human C5a [1071]. In addition to recruitment of neutrophils from the circulation, release of the mature neutrophil storage pool and upregulation of neutrophil production by the bone marrow may be required to provide sufficient numbers of neutrophils to contain the infection. As described in previous sections, entry of neutrophils and monocytes into tissues depends on the upregulation of adhesion molecules on the vascular endothelium by inflammatory mediators and cytokines and chemotactic factor–induced increases in the abundance and avidity of integrins on neutrophils and monocytes. Chemotactic factors also prime neutrophils and macrophages to ingest and kill GBS more efficiently. When ingested, GBS are exposed to a variety of potentially microbicidal products, including reactive oxygen metabolites, acidic pH, elastase, cathepsin G, and cationic proteins, as discussed previously. IL-12 facilitates IFN-γ production, and both cytokines enhance the resistance of neonatal rats to GBS infection [1072,1073]. The mechanism by which IFN-γ enhances resistance is unknown, and it is unknown whether IFN-γ contributes to protection in humans.

In cases in which GBS overwhelm neonatal defenses, septic shock may result, and this is the most frequent cause of death resulting from systemic infection owing to GBS in neonates. Septic shock results from systemic overproduction of inflammatory mediators, including TNF-α, IL-1, and IL-6, by phagocytes and other host cells. Encapsulated and unencapsulated type III GBS induce production of these cytokines by human monocytes in vitro [1074]. Lipoproteins released by GBS induce inflammatory mediator production after binding to TLR2 plus TLR6; other components of GBS induce these mediators through an as-yet undefined TLR or TLR-related receptor [1075]. GBS also likely activate NLRs, although this has not been directly shown. Neutralization of TNF-α enhances survival in animal models, even when begun 12 hours after inoculation with these organisms [1076]. Similarly, administration of IL-10, which inhibits production of TNF-α and other proinflammatory cytokines, enhances survival in animals [1077]. These findings suggest that excessive proinflammatory cytokine production is deleterious in the context of

GBS infection, but this has not been shown in human neonates. Treatment of sepsis in adults with a soluble TNF-α antagonist led to increased mortality in adults [1078].

## Neonatal Defenses

With rare exceptions [1079], neonatal GBS infection occurs only in infants who do not receive protective amounts of GBS type-specific antibodies from their mothers [1068,1080]. Although the concentrations of GBS type-specific IgG antibodies in cord sera are usually slightly less than in maternal sera at term, term neonates born to mothers with protective concentrations of IgG antibodies generally are protected. In infants born before 34 weeks of gestation, the amounts of GBS type-specific antibodies often are markedly less than in the mother [1081]; preterm neonates may not be protected even though their mothers' serum contains protective amounts of IgG antibodies.

Production of type-specific antibodies by infected neonates is unlikely to contribute to protection. Infected neonates commonly do not make detectable type-specific antibodies during the first month after infection; a few transiently synthesize IgM, but not IgG antibodies [1082]. By 3 months of postnatal age, sera from uninfected infants and from infants who had previous type III GBS infection usually contain type-specific IgM antibodies [1083,1084]. It is unclear, however, that these antibodies require the exposure of normal infants to type III GBS; they could develop naturally or result from a cross-reactive immune response to another source of antigens to which the infant is exposed postnatally.

In the absence of type-specific antibodies, subtle but cumulative deficits in numerous other host defense mechanisms probably contribute to the neonate's susceptibility to GBS. Type III GBS efficiently adhere to mucosal epithelial cells of neonates, particularly ill neonates [1085,1086]. Production of β-defensin and LL-37 antimicrobial peptides that are active against GBS by the skin of neonates is robust [9,10]. Production of these peptides by respiratory epithelial cells seems to be less, however, than that of adult cells at term and to be more clearly reduced in preterm neonates [28]. At birth, neonates also lack secretory IgA. Reduced amounts of surfactant apoprotein A in the lungs of preterm neonates, a paucity of alveolar macrophages in the lungs of term and particularly preterm neonates before birth, and diminished phagocytosis and killing of bacteria by these cells may also enable GBS to invade via the respiratory tract. Limitations in the generation of chemotactic factors or deficits in the chemotactic responses of neonatal neutrophils, or both, may result in delayed recruitment of neutrophils to sites of infection. When they reach sites of infection, neonatal neutrophils may kill bacteria less efficiently because of limited amounts of opsonins, because the local bacterial density has reached high levels, or because the microbicidal activity of neutrophils is decreased in certain neonates. To compound the problem, rapidly progressive infection can deplete the limited marrow neutrophil reserve.

Although the lack of type-specific antibodies and a multitude of subtle deficits in neonatal defenses together likely contribute to the neonate's predisposition to GBS disease, why does disease develop in less than 10% of infants who lack type-specific antibodies and are born to colonized mothers? At present, the answer to this question is incomplete. Among neonates who lack type-specific antibodies, the risk for development of GBS disease seems to be greater in neonates born to mothers with high-density genital tract colonization or GBS amnionitis and may vary with the virulence of the strain. It also is likely that variations in host defense competence between individuals contribute, such as differences in antibody-independent complement activation, and that these deficits are greater in more premature neonates [1087].

## Immunologic Interventions for Neonatal Group B Streptococcal Sepsis

As summarized in the preceding section, the principal host defense deficits that predispose the neonate to infections with GBS and other extracellular microbial pathogens seem to be a deficiency of opsonins, particularly protective antibodies, and a limited capacity to increase neutrophil production and mobilize neutrophils to sites of infection. Attempts have been made to address both of these deficits through immunologic interventions. There is at present no conclusive evidence, however, that any form of immunologic intervention for prevention or adjunctive therapy of bacterial or fungal infections in the neonate improves outcome.

### *Prevention*

Selective intrapartum chemoprophylaxis with penicillin or ampicillin has reduced the rate of early-onset disease owing to GBS by approximately 80%, but had no impact on the incidence of late-onset disease [1088]. This observation supports the importance of developing a vaccine that could be used to immunize women before conception or in the early part of the third trimester. Studies have shown that 80% to 93% of adults immunized with type Ia, Ib, II, III, and V capsular polysaccharide–protein conjugate vaccines respond with approximately fourfold titer increases, with geometric mean titers ranging from 2.7 μg/mL for type III to 18.3 μg/mL for type Ia [1089]. Vaccines that induce protective antibodies against shared protein antigens also show promise [1090]. Although this approach may not supplant the need to provide intrapartum chemoprophylaxis for very preterm neonates—born at less than 34 weeks of gestation before receiving passive maternal antibodies in amounts sufficient to provide protection—it is estimated that such an approach would prevent more than half of all neonatal GBS disease [1088].

Numerous studies have evaluated the efficacy of intravenous immunoglobulin (IVIG) for the prevention of nosocomial or late-onset pyogenic infections in premature neonates. A 1997 meta-analysis of 12 randomized controlled trials, which included 4933 infants, showed a slight but statistically significant reduction in the incidence of sepsis ($P < .02$) [1091]. A more recent meta-analysis by the Cochrane collaboration in 2001, which included 19 randomized controlled trials with a total of 4986 infants, found a 3% reduction in sepsis ($P = .02$) [1092]. The stringency with which sepsis was defined in these studies varied. Perhaps more important, IVIG prophylaxis had no effect on mortality rates.

A multicenter randomized controlled trial in premature neonates at increased risk because of total IgG concentrations less than 400 mg/dL found no significant reduction in sepsis or other tangible benefit of IVIG prophylaxis. Similarly, a trial of prophylactic administration of a polyclonal IVIG preparation derived from donors with high titers of antibody to surface adhesins of *S. aureus* and *Staphylococcus epidermidis* showed no impact on the incidence of sepsis attributable to these organisms, *Candida*, or other agents and no effect on mortality [1093]. The authors of these reports and others [1094] concluded that IVIG is not indicated for prophylaxis in preterm neonates and neonates with low birth weight because there is no effect on long-term outcome and little or no effect on short-term outcomes.

Recombinant G-CSF and GM-CSF augment granulocyte production and function in neonatal animals and provide some protection against challenge with pyogenic bacteria, including GBS, in neonatal animal models. These findings prompted clinical trials to determine if administration of recombinant G-CSF or GM-CSF to human neonates would result in increased levels of circulating neutrophils and protect at-risk neonates from sepsis. Four randomized trials of prophylaxis with recombinant GM-CSF and one comparative observational study of prophylaxis with recombinant G-CSF were conducted [80,1095–1097]. These studies showed that G-CSF and GM-CSF increase circulating neutrophil counts and seem to be well tolerated.

The most recent and largest randomized trial of 280 neonates and a meta-analysis of the results from the four GM-CSF trials showed no reduction in the rate of sepsis or mortality [1096]. The small, nonrandomized observational study found that prophylactic administration of G-CSF to neutropenic infants with low birth weight born to mothers with preeclampsia led to a reduction in proven bacterial infections in these patients [1098]. No randomized controlled trials with G-CSF have been conducted, however, so its utility as a prophylactic agent is essentially untested. The evidence does not support the prophylactic use of G-CSF or GM-CSF in neonates.

## Adjunctive Therapy of Pyogenic Infections

### Passive Antibody

Over the past 2 decades, various studies have been performed to determine whether IVIG would improve the outcome in neonates with suspected or proven sepsis. These studies have differed in design and have been performed in countries with differing rates of neonatal sepsis, management approaches, and preparations of IVIG. The Cochrane collaboration performed a meta-analysis of 13 randomized controlled trials from seven countries involving neonates with suspected or proven invasive bacterial or fungal infections [1092]. In the six trials ($N = 318$ subjects) that included neonates with clinically suspected infection, IVIG had a marginal effect on mortality rate (relative risk 0.63, 95% confidence interval 0.41% to 1.00%, $P = .05$). In the seven trials ($N = 262$ subjects) that evaluated outcome only in neonates subsequently proven to have invasive infections, mortality also was marginally reduced by IVIG (relative risk 0.51, 95% confidence interval 0.31% to 0.98%, $P = .04$). The authors concluded that the marginal statistical significance and the variability in study design and quality do not allow firm conclusions to be made at the present time. To address this uncertainty, an international neonatal immunotherapy study with a target enrollment of approximately 5000 has been proposed [1094]. Nonetheless, there is currently insufficient evidence to support the routine use of IVIG in the management of neonatal sepsis.

### Neutrophil Transfusions

Neutrophil transfusions enhance survival rate in certain animal models of neonatal sepsis, but the clinical efficacy of neutrophil transfusion in human neonates with sepsis is uncertain. Three of five controlled studies showed statistically significant improvement in the survival rate for neonates receiving granulocyte transfusions compared with infants not receiving this therapy [1095]. Nonetheless, small sample sizes and differences in entry criteria for treatment and control groups, in methods of neutrophil preparation, in numbers of neutrophils per transfusion, in numbers of transfusions, and in bacterial pathogens causing disease preclude a meaningful meta-analysis of these studies. Although neutrophil storage pool depletion has been used as a selection criterion for neonates for whom transfusion may be beneficial, the difficulty in ascertainment of neutrophil storage pool size in clinical practice and the failure of this parameter to predict outcome in some studies make this measure an imperfect criterion in clinical practice. The utility of neutrophil transfusions is compromised further by the difficulty in obtaining these cells in a timely fashion and the potential complications of transfusions, including the risk of infection. For these reasons, neutrophil transfusions cannot be recommended as routine therapy for neonates with suspected or proven sepsis.

### Colony-Stimulating Factors

Administration of G-CSF to human neonates 26 to 40 weeks of gestational age with presumed early-onset sepsis was shown to increase significantly the numbers of circulating neutrophils, bone marrow neutrophil storage pool size, and neutrophil expression of CR3 receptors (CD11b through CD18) without adverse effects [1099–1101]. The 2003 Cochrane meta-analysis of all causes of mortality in 257 infants with suspected sepsis from seven randomized clinical trials showed, however, that survival was not improved by adjunctive treatment with G-CSF or GM-CSF; G-CSF was used in most of these studies [1172]. A subset analysis from three of these studies that included 97 infants with neutropenia (absolute neutrophil count $<1700/mm^3$) showed an apparent reduction in mortality (relative risk 0.34, 95% confidence interval 0.12% to 0.92%). In an earlier meta-analysis of five studies involving 73 neonates who received G-CSF and 82 controls by Bernstein and colleagues [1102], the mortality rate was significantly reduced ($P < .05$), but if data from two nonrandomized trials were excluded, there was no significant difference (observed risk 0.43, 95% confidence interval 0.14% to 1.23%, $P = .13$). No significant adverse effects of G-CSF adjunct therapy were noted in these

studies; also, one long-term follow-up study found no adverse effects. As with the meta-analyses of adjunct therapy of neonatal sepsis with IVIG, data regarding the use of G-CSF for adjunctive therapy of neonatal sepsis indicate that it is safe and might be useful in some situations. Nonetheless, evidence is currently insufficient to support the routine use of G-CSF or GM-CSF as adjunctive therapy in septic neonates.

## Summary

Substantial advances have occurred in the understanding of factors that compromise the neonate's defenses against bacterial infections. As a result of this information, numerous clinical trials have evaluated the use of IVIG, G-CSF, or GM-CSF for the prophylaxis or adjunctive treatment of neonatal infections. The results from these studies have been disappointing or inconclusive. To date, there is no established role for these or any other immunologic therapy in the prevention or treatment of bacterial or fungal infections in human neonates. The existing data are sufficient to conclude that the prophylactic use of IVIG is not cost-effective and that such use of GM-CSF is not beneficial. Conversely, randomized clinical trials to test the potential benefit of IVIG in septic neonates or G-CSF in septic, neutropenic neonates, or combinations of these agents as adjunctive therapies for neonatal sepsis may be indicated.

# VIRUSES: HERPES SIMPLEX VIRUS

## Overview of Host Defense Mechanisms

Effective viral host defense mechanisms of vertebrates typically depend on a combination of innate and adaptive immune mechanisms that are highly interlinked. Because viruses replicate intracellularly and potentially infect a wide range of cell types, generic antiviral mechanisms, such as those involving type I IFNs, are crucial for early control of infection. Innate and adaptive cellular mechanisms that control or block infection within cells, such as by NK cells and CD8 T cells, prevent spread of virus from cell to cell and are crucial for effective host defense. Antibody and complement also may modify viral expression, especially by preventing spread of virus into the central nervous system, but in most tissues the cellular immune response is crucial for control of viral replication and the elimination of virally infected cells. This section focuses on host defenses operative against HSV-1 and HSV-2, both of which cause strikingly more severe primary disease in neonates than in immunocompetent adults [1103].

HSV-1 and HSV-2 mostly are collectively referred to here as HSV because these two viruses are very closely related and, in most instances, have very similar pathogenic properties. HSV infection is severe in term infants infected at the time of parturition and in the uncommon cases when it is acquired in utero. Characteristically, HSV infection in neonates spreads rapidly to produce either disseminated or central nervous system disease. Enteroviral infections also are severe and may be fatal when acquired in the perinatal period and, similar to HSV infections, have a propensity to produce disseminated or central nervous system disease. Another similarity between HSV and enteroviral infections is that infection acquired after the neonatal period (after age 4 weeks) is typically effectively controlled, suggesting that common developmental limitations in antiviral immunity are responsible. Deficiencies in the function of neonatal NK cells and DCs probably are important contributors to poor early control of infection by the innate immune response. Neonates also may develop crucial antigen-specific T-cell responses to the virus too slowly to prevent the virus from producing irreparable tissue injury or death.

## Innate Immunity

The antiviral immune response generally can be divided into two phases. The first is an early, nonspecific phase (typically the first 5 to 7 days in HSV infection) involving innate immune mechanisms. This is followed by a later, antigen-specific phase involving adaptive immunity mediated by T cells and B cells and their products [1104]. The early phase is critical because infection either may be successfully contained or may disseminate throughout the host.

### *Interferons, Cytokines, and Their Induction by Toll-like Receptors*

HSV triggers high levels of type I IFN secretion by pDCs in a TLR9-dependent fashion [325] as the HSV double-stranded DNA genome is unmethylated at CpG dinucleotide residues. The secretion of high levels of IFN-$\alpha$ by pDCs results in a systemic antiviral state by binding to type I IFN receptors, which are almost ubiquitously expressed. This antiviral state enhances local adaptive immune responses, such as those mediated by B cells and T cells, as a result of a direct effect on these cells in secondary lymphoid tissue [1105]. The type I IFN receptor mediates its effects by the binding of a heterotrimeric complex of STAT-1, STAT-2, and IRF-9 to IFN-stimulated response elements (ISREs) of genomic DNA, influencing gene transcription [250]. STAT-1 also can homodimerize and bind to $\gamma$-IFN–activating sequences, which induce a distinct set of genes from the genes using ISREs. Because these STAT-1 homodimers (but not other STATs) and $\gamma$-IFN–activating sequence–regulated genes are activated when IFN-$\gamma$ binds to its specific receptor, type I IFN may potentially induce genes that are characteristic of IFN-$\gamma$ responses, but not vice versa. For antiviral host defense in humans, including to HSV, only the ISRE genes seem to be critical, however [1106,1107]. IL-28 and IL-29 (also known as IFNs $\lambda$), which are also induced by HSV infection and TLR9 engagement, also provide ISRE gene–dependent antiviral immunity after binding to a unique receptor distinct from the receptor for type I IFN [1108].

HSV induces the production of type I IFN and other cytokines after engagement of TLR3, which is expressed in cDCs, but not pDCs; fibroblasts; epithelial cells; and resident cells of the central nervous system, including microglia, astrocytes, and oligodendrocytes. Because TLR3 preferentially recognizes double-stranded RNA or surrogates, such as poly I:C, but not DNA, its

recognition of HSV may be the result of a symmetric transcription process that generates abundant amounts of viral double-stranded RNA [1109]. Genetic deficiency of either TLR3, owing to a dominant-negative–acting heterozygous mutation [1110], or UNC-93B [1111] results in a selective vulnerability of humans to primary HSV-1 encephalitis and not other infections. UNC-93B is a highly conserved 12-membrane spanning protein that is found in the endoplasmic reticulum and that is required for signaling for TLR3, TLR7, and TLR9. The importance of TLR3 in limiting the development of HSV encephalitis may be due to its higher levels of expression in the central nervous system than other TLRs that can recognize HSV.

Some HSV strains induce cytokine production by mononuclear cells and DCs in a TLR2-dependent manner [1112]. The TLR2 ligands expressed by HSV are unclear, but glycoproteins are plausible candidates because other herpesvirus glycoproteins, such as those of CMV, are recognized by TLR2 [1113]. The importance of TLR2 in human HSV infection also is suggested by the observation that certain genetic TLR2 polymorphisms are associated with increased shedding of HSV-2 and the frequency of genital lesions caused by this virus [1114]. A murine model of lethal HSV1 encephalitis infection found that brain inflammation and mortality were reduced in TLR2-deficient compared with wild-type neonatal mice [1112]. This protective effect of TLR2 deficiency was associated with markedly reduced levels of serum IL-6 and of brain tissue CCL2 compared with levels found in wild-type animals. There was a strong trend toward there being higher levels of HSV1 in brain tissue in TLR2-deficient animals early after infectious challenge, although this did not achieve statistical significance. Together, these results suggest that the TLR2-dependent induction of cytokines and chemokines by HSV can result in deleterious levels of proinflammatory cytokines and chemokines. A single study [1115] has also reported that cord BMCs produce substantially higher levels of IL-6 and IL-8 than adult peripheral BMCs in response to HSV infection in vitro, although whether this increased response is dependent on TLR2 has not been evaluated.

### Circulating and Cerebrospinal Fluid Levels of Cytokines and Chemokines in Human Herpes Simplex Virus Infection

Substantial amounts of type I IFNs are found in the tissues of HSV-infected humans, such as the cerebrospinal fluid of adults, children, and neonates with HSV encephalitis [1116–1118]. Although HSV efficiently induces type I IFN production, the virus is relatively resistant to its antiviral effects. This relative resistance may account for the limited effectiveness of type I IFNs in treating recurrences of established HSV infections, such as of the eye. The resistance may be due in part to the ability of the HSV ICP34.5 protein to interfere with the production of and cellular responsiveness to type I IFNs [1119]. HSV infection of certain human cell types also may inhibit type I IFN–mediated activation of the JAK/STAT pathway by inducing increased suppressor of cytokine signaling-3 [1120].

IFN-γ, which also has antiviral activity on numerous cell types, could also play a role in early innate immune control of HSV infection by its secretion from NK cells, NKT cells, and γδ T cells before the appearance of HSV-specific CD4 and CD8 T cells. There is little information on the circulating levels of IFN-γ in primary HSV infection or HSV reactivation in humans. Neither form of HSV infection seems to be more severe in individuals who have IFN-γ receptor genetic defects [554] or STAT1 mutations that selectively compromise IFN-γ–dependent STAT1 homodimer-directed transcription [1106]. An increased severity of HSV or other herpesvirus infections has also not been observed in genetic deficiency of the IL-12Rβ1 subunit, which impairs IL-12p70–dependent generation of $T_H1$ cells and IL-23–dependent $T_H17$ immunity [553,554,578].

Circulating IL-6 and soluble TNFR1 levels are markedly elevated in human neonates with systemic HSV infection, as is the circulating viral load, which can reach extremely high levels (i.e., a mean of $10^6$ viral genomes/mL of blood) [1121,1122]. The highest levels of these proteins and viral load are observed in cases that have a fatal outcome [1121,1122], but evidence for a direct involvement of soluble TNFR1, IL-6, or other cytokines that are elevated in the circulation in the morbidity or mortality of disseminated HSV in neonates [1103] is lacking. Although "overexuberant" cytokine and chemokine production, possibly by a TLR-dependent mechanism, could contribute to the sepsis-like syndrome, it is equally or more plausible that the sepsis-like syndrome of disseminated HSV is simply a reflection of an overwhelming viral infection, as indicated by the extremely high viral load [1121,1122], evidence of extensive coagulative necrosis of liver [1103], and detectable circulating levels of cytochrome *c* (also suggestive of extensive cell death) [1122]. The sensitivity of the liver to coagulative necrosis is not unique to the neonate and is part of the pathogenesis of cases of HSV hepatitis after primary infection in pregnant women and apparently immunocompetent adults. This suggests the importance of the prevention of HSV dissemination to the liver by innate or adaptive immune responses. A more complete assessment of circulating levels of cytokines and chemokines in neonatal HSV, particularly disseminated and central nervous system disease, might be helpful in understanding of disease pathogenesis and identifying particular cytokines that might be useful in adjunctive therapy (see later).

The induction of chemokines is an important early step in attracting leukocytes to mediate antiviral immune mechanisms and initiate antigen uptake and processing for the generation of the adaptive immune response. Elevated cerebrospinal fluid levels of the CC chemokines CCL2, CCL3, and CCL5 (RANTES) and of CXCL8 also have been documented in cases of adult human HSV encephalitis [1123], suggesting their role in central nervous system inflammation, but similar information for neonatal infection is limited.

### Mononuclear Phagocytes

Macrophages are likely to play an important role in the early and local containment of HSV infection by their secretion of cytokines and chemokines. HSV can directly

infect mononuclear phagocytes in vitro, but the resultant infection usually is nonpermissive and does not result in viral replication. Such nonreplicative infection may result in apoptosis [1124], which could limit antiviral immune mechanisms, such as cytokine production. The in vitro production of other cytokines by cells of the innate immune system that enhance NK-cell and $T_H1$ T-cell responses may be decreased in neonates. IL-12 and IL-15 production by mononuclear cells (presumably mainly by monocytes) from term neonates after stimulation with LPS was approximately 25% of that by adult cells [1125,1126]. Whether such cytokines are produced in amounts sufficient to limit NK-cell or T-cell immunity in neonates with HSV infection is unknown.

### Dendritic Cells

The in vivo role of human DCs in the control of HSV is poorly understood. HSV can efficiently replicate in immature, but not mature, moDCs, and infection decreases expression of cytokines, such as IL-12 and type I IFN [1127], and markers indicative of DC maturity, such as CD83 [1128]. These decreases are associated with a limited capacity of these cells to activate T cells in vitro [1127]. Similar limitations in type I IFN production and the capacity to activate T cells may apply to murine DCs that are exposed to HSV [1129]. Together, these findings suggest that DCs are not effectively activated by HSV infection and may be direct cellular targets of HSV-mediated immunosuppression. It is unclear, however, how frequently DCs are infected in vivo with HSV in humans. In addition, as a potential countermeasure against viral immunosuppression, human DCs can take up HSV-infected DCs that are undergoing apoptosis and effectively cross-present HSV antigens to CD8 T cells [1130,1131]. Based on murine studies, it is plausible that apoptotic HSV-infected Langerhans cells of the skin may be taken up by cDCs, which cross-present antigens to CD8 T cells in the draining lymph nodes [1132].

Little is known concerning the innate immune response during primary HSV infection in neonates, including that mediated by DCs. An older study [270] found that type I IFN production by peripheral BMCs and the frequency of IFN-α–producing cells (assayed by the ELISPOT technique) in response to fixed HSV were diminished compared with adults, particularly for prematurely born infants. The major cell type that produces type I IFN in this assay are pDCs, and, consistent with these results, a more recent study found diminished production of type I IFNs by neonatal pDCs in response to HSV-1, CMV, and TLR7 and TLR9 ligands [328]. The mechanisms for reduced cytokine production by neonatal pDCs may include decreased nuclear translocation of IRF7, most likely because of block in TLR-induced IRF7 phosphorylation.

Given the association of mutations of TLR3 in humans with an increased susceptibility to primary HSV encephalitis [1110], the function of TLR3 signaling in the neonate is of particular interest. TLR3 mRNA expression is upregulated by the differentiation of adult peripheral blood monocytes into moDCs, whereas cord blood monocytes have minimal increases in TLR3 after in vitro differentiation into DCs [1133]. Reduced TLR3 expression or TLR3-mediated signaling may also apply to cDCs of the neonate because circulating adult cDCs have substantially greater increases in CD40 and CD80 expression compared with cord blood cDCs in response to treatment with the TLR3 ligand poly I:C [271]. Whole-blood levels of IFN-α are also substantially lower in cord blood compared with adult peripheral blood after poly I:C treatment [271], and cDCs are likely to be the major source of IFN-α in this assay. Because poly I:C treatment of either monocytes or moDCs results in significantly greater increases in TLR3 mRNA expression by adult cells compared with neonatal cells [1133], these developmental differences in TLR3-mediated responses may be accentuated further after TLR3 ligand exposure in vivo. The mechanisms underlying reduced TLR3 gene expression by neonatal monocytes and cDCs and their relationship to the levels of TLR3 protein are unclear; whether such decreases apply to nonhematopoietic cells, such as those of the central nervous system, also is unclear.

Studies of signaling by other TLRs, such as TLR4 of neonatal mDCs and TLR9 of neonatal pDCs, suggest that neonatal DCs may have limitations in IRF3-regulated and IRF7-regulated transcription. In the case of IRF3, the ability of IRF3 that translocates to the nucleus to bind to DNA and to associate with transcriptional coactivators may be impaired; for IRF7, TLR-induced nuclear translocation may be reduced [328]. Because IRF3 is crucial for the production of IFN-β by TLR3 signaling, and IRF7 is key for IFN-α production by pDC TLR9 signaling [1134], these developmental limitations in IRF-dependent transcription could impair antiviral protection mediated by type I IFNs in neonatal HSV infection.

### Natural Killer Cells

NK cells provide a particularly important restraint on viral replication and dissemination before the appearance of adaptive immunity, as shown by the severity of primary infections with herpesviruses, including HSV and VZV, in patients with a selective lack of NK cells [1135]. Although the initial disease is severe, NK cell–deficient patients are able to clear virus eventually, presumably by T cell–mediated immunity (Lewis DB, Wilson CB, unpublished data). The importance of human NK cells in the control of HSV is also suggested by the markedly impaired NK-cell function of patients with Wiskott-Aldrich syndrome, who are highly prone to develop severe primary HSV infection [1135]. NK cell–derived cytokines, such as IFN-γ and TNF-α, have direct antiviral effects on HSV replication, and IFN-γ also increases MHC expression (class I and class II), which facilitates antigen presentation to CD4 and CD8 T cells. The presence of NK cell–derived IFN-γ during the early phases of naïve T-cell activation also may increase expression of the T-bet transcription factor and may favor T-cell differentiation into $T_H1$ cells. NK cells may accomplish this bias toward $T_H1$ differentiation of naïve CD4 T cells by localizing to antigenically stimulated lymph nodes in a CXCR3-dependent manner [1136]. IL-15, which has a key role in NK-cell development, is also a potent activator

of NK cells for enhanced cytotoxicity against most herpesviruses, including HSV [1137]. Exposure of human peripheral BMCs to HSV also upregulates NK-cell cytotoxicity by an IL-15–dependent mechanism [1138].

As discussed earlier, fetal and neonatal NK cells have reduced cytotoxic activity compared with NK cells of adults, including against HSV-infected [1139] or CMV-infected target cells [382]. The addition of activating cytokines to neonatal NK cells, such as IFN-α or IFN-γ, does not reliably increase cytolytic activity against HSV-infected targets, whereas adult NK cells have consistent and substantially increased cytotoxicity [1139]. Paralleling the reduction in natural cytotoxic activity of neonatal cells, ADCC of neonatal mononuclear cells is approximately 50% of that of adult mononuclear cells, including against HSV-infected targets [1104]. Decreased ADCC mediated by purified neonatal NK cells seems to be caused in part by an adhesion defect in the presence of antibody [378]. Cytokine production by NK cells is another potentially important mechanism of host defense against HSV. Neonatal NK cells produce IFN-γ as effectively as adult NK cells in response to exogenous IL-2 and HSV [1140] or to polyclonal stimulation with ionomycin and PMA [599]. The adequacy of neonatal NK-cell production of these and other cytokines in response to physiologic stimulation (e.g., with HSV-infected cell targets in the absence of exogenous cytokines) is unknown.

Regardless of the precise mechanism, reduced NK-cell cytolytic activity may be an important contributor to the pathogenesis of neonatal HSV infection as indicated in a neonatal murine model in which adoptively transferred human mononuclear cells from adults, but not neonates, provided protection after adoptive transfer [1104]. This model has also implicated deficits in IFN-γ production by neonatal mononuclear cells in limiting protection because the addition of IFN-γ restores the protection. The role of IFN-γ in controlling HSV infections in humans is unclear, however, because severe primary or recurrent HSV infection has not been reported as a major complication of patients with genetic deficiency of IFN-γ receptors or acquired autoantibodies against IFN-γ. No studies have directly compared NK-cell function against HSV targets in neonates versus adults with primary HSV infection, including after treatment with various immunostimulatory cytokines.

### γδ T Cells

γδ T cells, particularly cells bearing Vγ9Vδ2 TCRs, obtained from HSV-seropositive donors can lyse HSV-infected cells in a non-MHC–restricted manner. Vγ9Vδ2 γδ T cells are also a major portion of the T cells that infiltrate sites of human genital HSV infection [1141]. As is generally true for the Vγ9Vδ2 cell subset, these T cells are not HSV-specific, but recognize intracellular-derived metabolites that are produced in increased amounts as a result of cellular stress (see previous chapter section on γδ T cells). γδ T-cell clones derived from these intralesional T cells are capable of secreting IFN-γ, TNF-α, IL-8, CCL3, and CCL5 [1141], suggesting that they may exert antiviral activity and maintain inflammation at these sites of infection. The importance of γδ T cells in limiting HSV infection in humans, including neonates, is unclear, however, because immunodeficient states that selectively involve this cell lineage have not been identified.

## Adaptive Immunity

Adaptive immune responses mediated by HSV antigen–specific T cells and B cells are first detected 5 to 7 days after the onset of primary HSV infection in adult humans, with the peak response achieved at approximately 2 to 3 weeks after infection [808,809,1142]. Antigen-specific immunity does not eradicate infection (i.e., achieve sterile immunity), but rather terminates active viral replication and the acute infection. T cells play the crucial role in resolution of active HSV infection and the maintenance of viral latency. The general importance of T cells in the control of human HSV and other herpesvirus infections is indicated by the increased susceptibility of individuals with quantitative or qualitative T-cell defects to these infections. The relative importance of CD4 and CD8 T cells in HSV infections in humans, including at particular sites, is uncertain, however. B cells do not seem to be able to provide protection in the absence of T cells.

### Viral Inhibition of Antigen Presentation and Effect on T-Cell Immune Response

In view of the importance of MHC class I antigen presentation in antiviral control, it is not surprising that many herpesviruses, including HSV and CMV, have accumulated multiple gene products to inhibit MHC class I antigen presentation. Inhibition of the MHC class I pathway limits not only CD8 T cell–mediated cytotoxicity, but also the generation of CTL from naïve CD8 T cells, although the presence of HSV-specific CD8 T cells at sites of infection shows that this inhibition is ultimately overcome. HSV encodes a viral host shutoff protein that is an RNA endonuclease and is required for viral pathogenicity. This viral protein preferentially destroys cellular mRNA and decreases host cell protein synthesis, including MHC class I molecules. This downregulation of MHC class I limits CD8 T cell–mediated cytotoxicity of HSV-infected target cells, such as fibroblasts and keratinocytes [1143]. HSV also produces an immediate early ICP47 protein that binds to the TAP transporter and prevents the loading of peptides onto MHC class I molecules and the transport of MHC class I molecules to the cell surface [1144].

The importance of selective inhibition of MHC class I antigen presentation in the pathogenicity of HSV has not yet been formally tested in vivo, but NK cells and HSV antigen–specific CD4 T cells are detected earlier than antigen-specific CD8 T cells in lesions of adult humans with recurrent HSV-2 disease [1145]. IFN-γ produced by infiltrating NK and CD4 T cells may help override the inhibitory effects of ICP47 on MHC class I expression, allowing the subsequent eradication of virus by CD8 T cells, which increase in lesions around the time of viral clearance. When HSV-specific CD8 T cells arrive at local sites of infection, they may persist, providing relative resistance to reinfection. HSV infection also results in marked reductions in the expression of invariant chains, which is required for MHC class II maturation

during antigen processing and its ultimate expression on the cell surface. The RNA endonuclease activity of the viral host shutoff protein may also decrease MHC class II expression directly. Together, these mechanisms may account for the observation that HSV infection in mice results in central nervous system lesions in which MHC class II expression remains intracellular, reducing the chance of detection by CD4 T cells [1146].

In addition to its well-known inhibition of MHC class I antigen presentation, HSV infection of neonatal monocytes [1147], moDCs [1148], or B cells [1149] can block the ability of these cells to activate CD4 T cells. As discussed previously, the extent to which HSV directly infects DCs and other APCs in vivo is unclear.

### *CD4 T Cells*

CD4 T cells may help control HSV infection by directly lysing HSV-infected cells that express viral peptides on MHC class II molecules [1145,1150,1151] and by inhibiting viral replication through the production of IFN-γ, TNF-α, and CD40 ligand. The IFN-γ–mediated increase in expression of the molecules involved in MHC class I antigen presentation also may help override the inhibition of MHC class I antigen presentation by HSV. Consistent with this idea, CD4 T cells and mononuclear phagocytes, and not CD8 T cells, are prominent initially in HSV-infected skin; later, CD8 T cells predominate [1145], most likely because CD4 T-cell IFN-γ production has restored surface expression of HSV peptides presented by MHC class I. CD40 ligand expression by CD4 T cells also is probably essential for HSV-specific antibody production by B cells and antibody isotype switching and for the ability of CD4 T cells to become long-term memory T cells [568], including those of the $T_H1$ subset [1152]. In rare patients with CD40 deficiency, production of IFN-γ by pDCs is decreased in response to HSV infection in vitro [1153], which strongly supports the idea that CD40 engagement by CD40 ligand contributes to human antiviral immunity. CD4 T cells also likely promote the generation and survival of anti-HSV effector CD8 T cells, as suggested by a large body of murine studies [1154]. They may even serve as APCs to HSV-specific CD8 T cells by bearing viral peptide/MHC complexes acquired from conventional APCs [1155].

CD4 T cells in HSV-seropositive adults have been identified in the circulation at a low frequency [1156] and from sites of recurrent infection in the skin, cervix, cornea, and retina. These CD4 T cells seem to be broad in their target recognition, with peptide epitopes derived from envelope glycoproteins, tegument (the layer between the envelope and capsid), and capsid [1157]. The HSV-specific circulating CD4 T-cell response has a predominant $T_H1$ cytokine profile [1158], consistent with the ability of the virus to induce type I IFN and IL-12p70 at sites of infection (discussed earlier), and this cytokine profile likely applies to HSV-specific CD4 T cells of the tissues. CD4 T cells with cytotoxic activity have been readily isolated from HSV seropositive adults by in vitro expansion from the circulation of HSV-infected individuals but their actual circulating frequency is unknown. Cytotoxicity is directed against various viral proteins, including glycoproteins of the lipid envelope, such as gB, gC, and gD [1151,1159,1160], and these viral glycoproteins may enter into the MHC class II antigen–processing endocytic pathway after first fusing with the host cell membrane. The kinetics of appearance of CD4 T cells in the tissues after primary HSV infection in adults is unknown.

In two studies in which T-cell responses in neonates and adults with primary HSV infection were compared [808,809], HSV-specific proliferation of peripheral BMCs and production of IFN-γ and TNF-α were markedly diminished and delayed in the neonates compared with these measures in the adults. The neonates did not achieve adult levels of these responses for 3 to 6 weeks after clinical presentation, whereas the adults developed robust responses within 1 week. In both studies, HSV antigen–specific responses by peripheral BMCs used viral antigen preparations that are processed mainly by the MHC class II pathway, rather than the class I pathway, mainly assaying CD4 T-cell function.

Other reports indicate that antigen-specific CD4 T-cell responses commonly are slow to develop in neonates infected perinatally or in utero with CMV [793,794]. Delayed CD4 T-cell responses to primary CMV infection also have been observed for older infants and young children compared with such responses in adults [579], suggesting that limitations in developing CD4 T-cell responses to at least some herpesviruses may continue beyond the neonatal period. Because, as discussed earlier, CD4 T cells provide multiple effector functions that may be crucial for the resolution of HSV infection—including direct antiviral cytokine production and help for CD8 T cells and B cells—this marked lag in development of HSV-specific CD4 T-cell responses in neonates could be an important contributor to the tendency of neonatal HSV infection to disseminate and to cause prolonged disease.

The basis for the delayed development of HSV antigen–specific CD4 T cells in neonates is unknown, but could reflect limitations intrinsic to these cells or limitations in APC function or both. Because immature DCs are primed for efficient antigen presentation by engagement of their CD40 molecule by CD40 ligand expressed by activated T cells, or by exposure to microbes or inflammatory cytokines induced by microbes, lack of prior exposure to microbes, which occurs in a cumulative manner after birth, might contribute to the increased susceptibility of the neonate to infection with HSV. A study showing reduced basal DC function in adult mice lacking functional TLR4 supports the idea that postnatal exposure to microbial products may contribute to the maturation of DC function [1161].

Intrinsic limitations in CD4 T-cell function might also contribute to the reduced and delayed HSV-specific CD4 T-cell immune response, such as decreased CD40 ligand by activated naïve CD4 T cells [533]. Other mechanisms intrinsic to the neonatal CD4 T cell, such as a decreased capacity to elevate $[Ca^{2+}]_I$ [611] and greater methylation of the IFN-γ gene [626], might also contribute. The tendency of activated neonatal CD4 T cells to become anergic, rather than develop into effector cells after exposure to bacterial superantigens [538], might also apply to HSV and contribute to the impaired antigen-specific

response. The neonatal murine model of HSV suggests that Tregs may contribute to the attenuated primary CD4 (and CD8) T-cell response [1162]. Whether Tregs play a similar inhibitory role in human primary HSV infection, including in neonates, is unclear, but Tregs can suppress recall responses by CD4 T cells to HSV antigens in vitro in adults [1163].

Neonates also have been reported to have a lower frequency of precursor T cells capable of responding to HSV and CMV [1164]. This finding is unlikely to be due to a limitation in the diversity of the αβ-TCR repertoire [454,456,457] and is more likely to be an artifact of in vitro culture conditions that may favor the survival of adult rather than neonatal T cells.

### CD8 T Cells

The efficient clearance of most viral infections depends on CD8 T cell–mediated cytotoxicity, in which infected target cells are induced to undergo apoptosis by the secretion of perforin and granzymes or the engagement of Fas by Fas-ligand (see Fig. 4–13). Direct evidence for the importance of CD8 T cells in the control of herpesvirus infections in humans comes from studies showing that the adoptive transfer of donor-derived CD8 T cells against CMV or EBV provides protection of hematopoietic cell transplant recipients from primary infection with these viruses. Murine studies indicate that CD8 T cells are key in resolving established lytic infections of the skin and nerves and in preventing spread of HSV from reactivation of sensory neurons. These roles also likely apply to the human CD8 T-cell response because HSV-specific CD8 T cells with features of effector memory cells are highly concentrated around sensory ganglia, such as those of the trigeminal nerve [1165]. Latent HSV infection is associated with a persistent and compartmentalized response that is likely directly involved in maintaining latency. These CD8 T cells may rely principally on nonlytic mechanisms for preventing HSV reactivation, including the production of IFN-γ; HSV may also express antiapoptotic proteins that also protect the neuron from CD8 T-cell perforin/granzyme B-mediated cell death [1166].

In HSV-seropositive adults with chronic infection, HSV-specific CD8 T cells are found mainly at sites of local recurrence of virus, such as the skin adjacent to the genital tract and the cervix [1167] and the cornea [1168]. At sites of healed genital lesions, CD8 T cells seem to persist, and studies suggest that HSV reactivation is frequent, but asymptomatic [1169] owing to active control by these local T-cell populations [1167]. By contrast, HSV-specific CD8 T cells are not detectable in the circulation with use of intracellular cytokine staining after stimulation with whole HSV [1156], but can be expanded in vitro from the blood of HSV-immune donors. An analysis of CD8 T cells using ELISPOT assays and overlying peptide pools have revealed a much broader CD8 T-cell response in individuals with genital HSV-2 infection, which includes all virion components [1170]. As for CD4 T cells, the CD8 T-cell immune response to primary HSV infection in adults is not well characterized.

To the best of our knowledge, there are no published studies of antigen-specific cytotoxic T-cell responses in the fetus, neonate, or young infant in response to HSV. This lack reflects, in part, the technical difficulties of performing classic cytotoxicity assays, which require HLA-matched or autologous virally infected target cells. This limitation might be overcome by newer approaches, such as detection of viral antigen–specific CD8 T cells identified using HSV peptide–class I HLA tetramers, particularly at local sites of HSV replication, such as cutaneous lesions [1171]. The kinetics of accumulation and tissue distribution of HSV-specific CD8 T cells in primary HSV infection is unknown. In a murine model of primary neonatal HSV using a replication-defective virus, which limits any adverse effects on T-cell priming from overwhelming infection, CD8 T cells with full effector activity, such as IFN-γ secretion, were slow to develop compared with HSV-infected adult mice [1162].

As discussed in detail in the section on T-cell response to congenital infection, studies of congenital CMV infection using CMV peptide–HLA-A2 tetramers found a robust response in the fetus, neonate, and young infant in terms of frequency of CD8 T cells and their function [663]. Although this finding suggests that strong stimulation, particularly if persistent, may induce virus-specific CD8 T-cell responses in the fetus, it does not exclude a potential lag in the appearance of CD8 T cells in the fetus or perinatally infected infant compared with adults with primary CMV. More recent studies suggest that CMV-specific CD8 T cells of the fetus may not be as diverse in terms of recognition of viral antigens and may have reduced IFN-γ secretion compared with the cells of pregnant women [665].

Evidence from perinatal HIV-1 infection also suggests such a lag in the appearance of CD8 T cell–mediated cytotoxicity and cytokine production, recognizing a diverse repertoire of viral antigens compared with adults with primary HIV-1 infection [818,820,1172]. The potential for a general lag in CD8 T-cell immunity also is suggested by older studies, which found that naïve CD8 T cells of the fetus and neonate generate less CTL activity than analogous adult cells after activation and culture in vitro. As indicated by the data on HSV-specific CD4 T-cell responses, a lag of days to weeks in the development of HSV-specific CD8 T-cell immunity after primary infection would likely be a major contributor to the morbidity of this infection in neonates.

### Chemotactic and Homing Receptor Expression by Viral Antigen–Specific T Cells

In established HSV infection, most recurrences of viral replication occur in keratinocytes found at epithelial sites, such as the skin and genitourinary mucosa. During these recurrences, virus-specific CD4 T cells and NK cells may infiltrate the sites by 48 hours after the appearance of lesions. Infiltration by these cells is followed several days later by the appearance of virus-specific CD8 T cells, which is associated with viral clearance [1145]. Many of the HSV-specific CD8 T cells at these sites express CLA [1173], an adhesion molecule that is involved in homing of T cells to skin and other tissues that contain keratinocytes, and it is likely that HSV-specific T cells that enter other sites of viral replication, such as the

central nervous system during HSV encephalitis, use a distinct combination of homing and chemotactic receptors (e.g., CCR2 and CCR5) to achieve selective trafficking [1174]. Other chemokine and homing receptor combinations are likely to be involved in trafficking of HSV-specific T cells to the liver and gastrointestinal tract in cases of disseminated disease.

Human neonatal naïve T cells differ from cells of adults in that they do not increase CXCR3 expression and decrease CCR7 expression after activation by anti-CD3 and anti-CD28 monoclonal antibodies [488,667]. CXCR3 facilitates T-cell trafficking to inflamed tissues that have been exposed to IFN-$\gamma$, whereas CCR7 mediates entry into lymphoid tissues in response to the CCL19 and CCL21 chemokines. These findings suggest that activated neonatal T cells may be limited in their capacity to traffic to nonlymphoid sites of inflammation, such as sites of HSV infection.

### B-Cell Immunity and Antibody-Dependent Cellular Cytotoxicity

Although preexisting antibody (e.g., that induced by vaccination) can prevent certain viral infections, antibody probably plays a limited role in the control of viral infections that are established. This limitation probably also applies to human herpesvirus infections because patients with X-linked agammaglobulinemia, who lack mature B cells and antibody production, generally are not more susceptible to these pathogens. Nonetheless, antibody may serve an auxiliary role in HSV host defense, particularly when cellular components of the response are deficient, such as in the human neonate. Antibody also may be important for prevention of dissemination of viral infections to the central nervous system, as has been well documented in agammaglobulinemic or hypogammaglobulinemic patients, who can develop paralytic poliomyelitis or severe chronic encephalitis with echoviruses or coxsackieviruses [1175].

Human HSV infection results in the induction of antibodies against a diverse set of HSV proteins, including surface glycoproteins involved in cell attachment and entry [1176]. The production of most HSV-specific antibodies by B cells is T cell–dependent. If antibody is passively acquired, as in the case of maternal-to-fetal transfer, humoral immunity may exist independently of T-cell immunity. Under relatively physiologic conditions, IgG and alternative pathway complement components can coat the surfaces of some viruses, including HSV, effectively neutralizing their infectivity, possibly by preventing their attachment or fusion with cell membranes. Antibodies also can react with viral proteins found on the surface of infected cells, and IgG and complement components can lyse in vitro human cells infected with many different viruses, including HSV. The importance of complement in viral host defense in humans is uncertain, however, because serious viral infection is not a feature seen in patients with severe inherited complement deficiency [1177].

A potentially more effective system for the elimination of virus-infected cells by specific antibody is by ADCC, with NK cells probably being the most efficient ADCC effector cells [1178]; the specificity of cytotoxicity is probably due to the specific recognition by antibody of viral antigens present on the infected cell surface. In vitro, ADCC requires relatively low concentrations of antibody and occurs rapidly (within hours), making it less likely that the virus would have had sufficient time to produce infectious particles. ADCC mediated by all types of effector cells is upregulated by cytokines, such as IFN-$\gamma$, type I IFNs, IL-12, and IL-15 [1179–1181]. In vitro ADCC activity correlates in some cases with protection against serious viral infections in humans and in animal models, but it is uncertain to what extent this protection is due to ADCC occurring in vivo.

Neonates have a modestly reduced antibody response, particularly for IgG, compared with older infants to most protein neoantigens, whereas IgM responses are similar. These decreased responses and isotype switching may be due, at least in part, to decreased expression of CD40 ligand by neonatal naïve CD4 T cells during their initial interaction with APCs [533]. Although these limitations in antibody response to T cell–dependent antigens may resolve by early infancy, they probably apply to HSV-specific antibodies made in response to neonatal HSV infection. Assuming that HSV-specific antibody that is neutralizing or involved in ADCC contributes to the control of primary HSV infection in humans, it is possible that limitations in isotype switching from IgM to IgG or a slower rate of somatic hypermutation of IgG responses could contribute to the severity of neonatal infection.

The neonate also is partially protected from infection by passive maternal IgG antibody, transferred predominantly during the third trimester of pregnancy. Fetal IgG concentrations are equal to or higher than maternal concentrations after 34 weeks of gestation, reflecting active transport mechanisms. In newborns with gestational age less than 38 weeks, a greater fraction of this maternally derived HSV-specific IgG may enter into the central nervous system [1182], reflecting a generally less effective blood-brain barrier. The risk of transmission of HSV from mother to infant in cases of primary or initial maternal infection is much higher (approximately 35%) than in cases of recurrent maternal infection. This difference may reflect in part lesser amounts of virus in the maternal genital tract in recurrent infection, but also may be due to protection by passively acquired HSV type-specific antibody, particularly to glycoprotein G [1183].

Kohl and colleagues [1184] also have shown that HSV-infected infants with greater concentrations of ADCC antibody had less severe disease compared with other infants with HSV infection. In otherwise healthy adults and older children with primary HSV infection, who by definition lack antibody to HSV, severe disease does not develop, as it does in neonates with primary infection. This finding indicates that the deficits intrinsic to the neonate are the important factors predisposing to severe infection. Nevertheless, passively acquired antibody may play a role in decreasing transmission or ameliorating disease severity.

## Adjunctive Therapy and Vaccination for Herpesvirus Infections

The foregoing studies raise the possibility that neonates could be passively protected by administration of antibody to HSV, particularly antibody that would facilitate ADCC. In vitro studies also suggest that polyclonal

antibodies or mAbs could potentially be protective by directly blocking HSV transmission from neurons to epithelial cells [1185]. Passive antibody can provide substantial protection from a low-inoculum HSV challenge in the absence of type I IFN signaling and T cells and B cells, by IL-12–dependent and IFN-γ–dependent mechanisms [1186], at least in mice. Human mAbs, murine mAbs that have been humanized, or specific hyperimmunoglobulin could potentially be employed for this purpose. The phage display technique has been used to select human mAbs with an ability to neutralize either HSV-1 or HSV-2 effectively at a relatively low concentration in vitro [1187], but it remains to be seen if these or related antibodies would be efficacious in limiting the extent of primary HSV infection in humans.

The unique capacity of IFN-γ to endow human neonatal BMCs with the ability to protect neonatal mice from infection suggests that exogenous IFN-γ also may be a potentially useful means to enhance the human neonate's resistance to HSV. In the experimental models described by Kohl [1104], passive immunotherapy must be given before or at the time of infection, however. Such therapy, if administered after infection is established, may be less effective, at least in controlling virally induced tissue damage. In addition, unanticipated fatal toxicity from early studies administering IL-12 to adult cancer patients [1188] indicates caution in the use of exogenous cytokine therapy in the seriously ill neonate; this is particularly true for IFN-γ because IL-12–induced IFN-γ has been implicated as the cause of such IL-12 toxicity [1189]. There is as yet no direct evidence that the initial innate immune response of the neonate to HSV infection is deficient in terms of cytokine production (e.g., for IL-12, TNF-α, and IFN-γ) derived from cells other than T cells.

Additional concerns about the use of exogenous cytokines comes from one study [1115] that reported cord BMCs produce substantially higher levels of IL-6 and IL-8 than adult peripheral BMCs in response to HSV infection in vitro. Based on this observation and results from a murine HSV model in which inflammation and mortality were reduced in TLR2-deficient neonatal mice [1112], it is argued that HSV induces overexuberant levels of proinflammatory cytokines in a TLR2-dependent manner, contributing to the sepsis-like syndrome of disseminated neonatal HSV infection. Consistent with this idea, circulating IL-6 and soluble TNFR1 levels are highly elevated in neonates with disseminated HSV infection, but the importance of IL-6 in neonatal HSV infection morbidity and mortality is unclear. More complete evaluation of the circulating levels of cytokines and chemokines in neonatal HSV might help to address the importance of impaired production versus overproduction of these immune regulators in pathogenesis.

Facilitating the more rapid development of antigen-specific CD4 and CD8 T cells with appropriate effector function might be a more physiologic approach, allowing these cells and the cytokines they produce to localize properly to the sites of infection. Further elucidation of the cellular and molecular mechanisms that underlie the lag in the development of antigen-specific immunity in the neonate in response to HSV may help in devising therapies to overcome these limitations in host defenses.

### Vaccination

Preventing the acquisition of genital HSV infection by women of childbearing age would markedly reduce neonatal HSV infection. HSV-2 vaccines employing recombinant glycoproteins, such as glycoprotein D2 in combination with alum and monophosphoryl lipid adjuvants, were effective in preventing acquisition of infection in women, but not men, who were initially HSV-2–seronegative [1190]. The reason for these sex differences is unclear, but HSV-seropositive women have been shown to have higher levels of HSV glycoprotein D–specific CD4 T cells than men [1160]. Although these vaccines have induced high levels of IgG antibodies against the glycoprotein immunogens, these antibodies may not efficiently mediate ADCC [1191]. If ADCC is important in preventing maternal-to-neonatal HSV transmission, these vaccines are unlikely to be beneficial in reducing neonatal HSV disease when used in the context of women who are already HSV-2–seropositive. With the growing recognition of the importance of HSV-specific CD8 T cells in maintaining latency and limiting shedding and spread from sites of reactivation, numerous strategies are also being pursued to increase the CD8 T-cell response to other HSV proteins [1192].

## NONVIRAL INTRACELLULAR PATHOGENS: *TOXOPLASMA GONDII*

### Host Defense Mechanisms

In addition to viruses, certain nonviral intracellular pathogens can replicate within cells and cause severe fetal or neonatal infection. These pathogens include *Salmonella* species, *Listeria monocytogenes*, and *M. tuberculosis*, which are facultative intracellular pathogens, and *T. gondii* and *Chlamydia trachomatis*, which are obligate intracellular pathogens. In contrast to pyogenic bacteria, for which phagocytosis usually results in death, phagocytosis of these pathogens is a means of entry into an intracellular haven. Each of these pathogens readily infects tissue macrophages of the reticuloendothelial system. In addition, *T. gondii* can infect virtually any nucleated mammalian cell type, and this nonspecificity has important consequences for the pathogenesis of toxoplasmosis. The following discussion of host defense mechanisms focuses primarily on *T. gondii*. Relevant information from studies of *L. monocytogenes* is included.

During acute toxoplasmosis in humans, replication of tachyzoites occurs intracellularly. A 30-kDa tachyzoite surface protein, P30, seems to be involved in the initial attachment of *T. gondii* to host cells [1193]. Antibodies frequently are made against this protein after infection and constitute a basis for serodiagnosis [1193,1194]. Intracellular *T. gondii* organisms are found principally in specialized parasitophorous vacuoles [1195]. These vacuoles, from which lysosomal components and host plasma membrane proteins are excluded, allow the free exchange of nutrients with the host cell cytoplasm, facilitating parasite replication [1196]. Cellular invasion by tachyzoites occurs without generating a respiratory burst in human macrophages [1197] or activating microbicidal nitric oxide production in murine macrophages [1198].

In response to adverse intracellular conditions that slow its replication [1199], the tachyzoite is induced to convert into a less metabolically active form, the bradyzoite. Bradyzoites can persist in many tissues for years or decades in the form of cysts. As discussed later, limiting chronic *T. gondii* infection to this quiescent state depends on antigen-specific cellular immunity; acquired T-cell immunodeficiency can allow bradyzoites to reconvert to tachyzoites that resume invasive infection.

Murine studies suggest that the control of acute infection by *T. gondii* and other nonviral intracellular pathogens is critically dependent on IFN-γ and $T_H1$ T cells, which activate macrophages to control the infection [1200,1201]. In the early stages of infection, *T. gondii* tachyzoites or products they secrete induce DCs or mononuclear phagocytes to produce cytokines, including IL-1, IL-12, IL-15, IL-18, and TNF. These cytokines induce NK cells to produce IFN-γ. NK cell–derived IFN-γ increases toxoplasmacidal activity of mononuclear phagocytes, helping to limit the initial extent of infection. IFN-γ produced by NK cells, in conjunction with IL-12 and IL-18 produced by mononuclear phagocytes and DCs, also favors the differentiation of antigen-specific $CD4^+$ T cells into $T_H1$ effector T cells that secrete large amounts of IFN-γ. $T_H1$ effector T cells produce IFN-γ that contains the parasite during the late phase of acute infection and helps limit the spread of infection in tissues should *T. gondii* bradyzoites later reactivate into tachyzoites. T cells and the IFN-γ they produce and IL-12, IL-15, and IL-23 produced by non–T cells that sustain $T_H1$ responses all seem to be essential for the lifelong control of reactivation, as shown from studies in chronically infected mice. In addition, IL-27 plays a crucial role in preventing the induction of $T_H17$ responses and the severe neuroinflammation they induce.

*T. gondii* actively inhibits these protective responses in several ways. *T. gondii* inhibits signaling pathways involved in the induction of IL-12 and TNF-α [1202]. This inhibition may account for the observation that infection of human mononuclear phagocytes and DCs with *T. gondii* induces very little IL-12, whereas the production of IL-12 can be markedly upregulated by engagement of CD40 on these cells by CD40 ligand on activated T cells [1202–1204]. Inhibition of IL-12 and TNF-α production by *T. gondii* may allow it to evade initial activation of protective immunity or may be an important mechanism by which the organism avoids inducing an excessive and potentially lethal inflammatory response [1202,1205]. Consistent with the latter possibility, *T. gondii* counters the induction of proinflammatory cytokines in mice by inducing the production of IL-27 and IL-10, which dampen the production of IL-17, IL-12, TNF-α, and IFN-γ and prevent lethal inflammatory responses to *T. gondii* [1201,1206].

The crucial role of macrophages in resistance to intracellular nonviral pathogens was first shown in animal studies of *L. monocytogenes* in which depletion of macrophages increased susceptibility [1207]. In the first days of infection, the rate at which monocytes are recruited to the site of infection and the microbicidal activity of these cells correlate with the control of *T. gondii* in animals [1208]. Infection of human monocytes by *T. gondii* tachyzoites also results in the induction of CD80 and increased expression of CD86 [1203]. The increased expression of these costimulatory molecules may enhance proliferation and IFN-γ production by T cells early in *T. gondii* infection and may assist in the differentiation of $T_H1$ effector cells from naïve T cells [1203].

Generally, the microbicidal activity of human monocytes against *T. gondii* is greater than that of macrophages [1209,1210]. In vitro studies with mononuclear phagocytes or microglial cells, which are mononuclear phagocytes of the central nervous system, show that oxidative and nonoxidative mechanisms are involved in limiting intracellular *T. gondii* replication. Cytokines are critical regulators of mononuclear phagocyte activity. IFN-γ produced by activated T cells and NK cells activates macrophage toxoplasmacidal activity in concert with CD40 ligand and TNF-α [1200,1211]. Activated macrophages kill and limit the intracellular replication of *T. gondii* by oxygen-dependent and oxygen-independent mechanisms. The latter include the induction of the enzyme indoleamine 2,3-dioxygenase, which leads to tryptophan degradation and deprives replicating *T. gondii* of this essential nutrient [1212,1213]. The relative importance of these mechanisms in humans is unclear.

The critical importance of $CD4^+$ T lymphocytes in protection against *T. gondii* is shown by the increased prevalence and severity of infection in patients with acquired immunodeficiency syndrome (AIDS). Similarly, mice with genetic T-cell immunodeficiencies are unable to control this infection. The importance of $CD4^+$ and $CD8^+$ T cells in mice depends on the phase of infection. In acute infection, $CD8^+$ T cells seem to be more protective than $CD4^+$ T cells [1214]. Both populations are necessary to limit the extent of central nervous system infection in the brain [1215], and $CD4^+$ T cells are required for the development of long-term protective immunity [1216].

Although antibodies seem to play little or no role in defense against *L. monocytogenes* [1217], antibodies probably make some contribution to defense against *T. gondii*. Nonetheless, T cell–deficient mice are much more susceptible than antibody-deficient animals and are not protected by antibody. The fact that *T. gondii* encephalitis in adult patients with AIDS typically develops by recrudescence of latent infection despite the presence of preexisting anti–*T. gondii* antibodies [1218] underscores the importance of T cells rather than B cells in the control of chronic infection with this pathogen.

## Fetal and Neonatal Defenses

Information regarding the innate immune response of the human fetus and neonate to *T. gondii* is limited. Neonatal monocytes can ingest and kill *T. gondii* [207,208]. Monocyte-derived and placental macrophages from human neonates are activated by IFN-γ to kill or restrict the growth of *T. gondii* as effectively as cells from adults [207,1219]. Nonetheless, it is likely that other limitations in innate immunity contribute to the increased susceptibility of the human fetus to *T. gondii* infection. Studies in neonatal rodents, which are highly susceptible to infection with *L. monocytogenes*, are consistent with this possibility. Administration of recombinant IFN-γ to neonatal

mice or rats before or at the time of infection protects them from acute infection and allows the development of protective immunity [1220,1221]. By contrast, administration of TNF-α protects adult, but not neonatal, rats, whereas coadministration of suboptimal doses of IFN-γ and TNF-α protects neonates. In these studies, acquisition of resistance to infection correlated with acquisition of adult competence for TNF-α production [1220]. The ontogeny of the immune responses in neonatal rodents and humans is substantially different, however, and the relevance of these findings for the human fetus and neonate is unclear.

Because T cell–mediated immunity plays a paramount and lifelong role in the control of *T. gondii* infection after acquisition of infection, differences in T-cell responses by the fetus and neonate (described in detail in chapter section on "T-Cell Development and Function in the Fetus and Neonate") are likely to be an important factor in their greater susceptibility compared with adults. In humans, *T. gondii*, similar to congenital viral pathogens such as CMV, is much more likely to produce severe fetal injury when the mother acquires primary infection early in pregnancy. The most severely damaged infants are likely to have acquired infection during the first trimester, when their numbers of T cells and their αβ-TCR repertoire for antigen recognition are limited compared with the fetus in the latter half of gestation. Nonetheless, αβ-TCR repertoire limitations are unlikely to be an important predisposing factor in most cases of congenital toxoplasmosis because severe sequelae do occur in fetuses infected during mid-gestation to late gestation, and sequelae ultimately develop in most infants infected at any time during gestation. Similarly, *L. monocytogenes* infection occurring in infants in the latter part of gestation usually is severe. This line of evidence suggests that mechanisms acting to contain *T. gondii* and *L. monocytogenes* infection are still immature in late gestation and at term relative to the mechanisms of older individuals.

These immature mechanisms are likely to include T-cell extrinsic differences, including diminished production of IL-12, type I IFNs and other $T_H1$ promoting cytokines by fetal and neonatal APCs, and T-cell intrinsic differences, which are described in detail in the section "T-Cell Development and Function in the Fetus and Neonate." These differences may include the greater tendency for neonatal T cells to acquire or sustain IL-10 and IL-4 production, relative to IFN-γ production, and lesser initial expression of CD40 ligand. Together, these differences may impede their ability to activate macrophages. In the case of IFN-γ, the predominance in the fetus and neonate of RTEs may contribute to this immaturity in cytokine secretion.

As noted subsequently, the acquisition of antigen-specific CD4 T-cell responses in utero in response to infection with *T. gondii* and other causes of congenital infection is often delayed. In vitro studies suggest that deficiencies of DC function and activation and differentiation of naïve $CD4^+$ T cells into memory/effector T cells may be contributory. Particularly in the mid-gestation fetus, Tregs are abundant and fully functional relative to other T cells and may help to delay the development of antigen-specific T-cell responses. The relatively less efficient induction of CXCR3, which is a hallmark of $T_H1$ cells and aids in their recruitment into infected tissues, and tendency to retain expression of CCR7, which facilitates continued trafficking to lymph nodes, may impair the delivery of neonatal CD4 effector T cells to sites of *T. gondii* infection. The severe brain injury observed in congenital *T. gondii* infection may result from unchecked parasite growth owing to impaired $T_H1$ immunity, impaired regulation of neuroinflammation, or both. In this regard, it would be interesting to know whether the congenitally infected fetus and neonate have impaired IL-27 production and excessive $T_H17$ responses, which have been associated with excessive neuroinflammation in mice [1206], but there are at present no data addressing this possibility.

*T. gondii*–specific memory $CD4^+$ T-cell responses may be delayed in their appearance in congenital toxoplasmosis and may not be detectable until weeks or months after birth. McLeod and colleagues [797] found that lymphocyte proliferation in response to *T. gondii* antigens, which primarily detects responses by $CD4^+$ T cells, was below the limit of detection in 11 of 25 congenitally infected infants younger than 1 year of age. The most severely affected infants were more likely to have undetectable or low antigen-specific T-cell responses. When memory T cells were first detected by lymphocyte proliferation assays in congenitally infected children, their capacity to produce IL-2 and IFN-γ often was less than that of memory T cells from adults with postnatal *T. gondii* infection [797].

Results consistent with these were reported by another group [1222]. Fatoohi and colleagues [1223] found that anti–*T. gondii* T-cell responses (determined using a different and less standardized assay) were lower in eight congenitally infected infants younger than 1 year of age than in individuals with acquired *T. gondii* infection and congenitally infected children studied when they were older than 1 year of age. Nonetheless, anti–*T. gondii* T-cell responses were detectable in most of the congenitally infected infants younger than 1 year of age by this assay. Ciardelli and coworkers [1224] also found that greater than 90% of congenitally infected infants less than 90 days of age had detectable T-cell proliferation and IFN-γ production in response to *T. gondii* antigen. The basis for the differences between these studies is unknown. Nonetheless, these data suggest that antigen-specific $CD4^+$ T-cell responses may develop more slowly or be diminished in some infants with congenital *T. gondii* infection.

A similar impairment or lag, or both, in the development of antigen-specific $CD4^+$ T-cell responses has been observed in infants with congenital infection caused by *T. pallidum*, CMV, VZV, or rubella virus [793–797,1225,1226] and, as discussed earlier, in neonates infected postnatally with HSV [809,811]. Similarly, Tu and colleagues [579] found that antigen-specific $CD4^+$ T-cell responses may be low in infants and young children with postnatally acquired CMV infection until active viral replication ceases, whereas antigen-specific $CD8^+$ T-cell responses are detectable much earlier. The basis for the initially poor $CD4^+$ T-cell response in these

infections is unknown. Regardless of the precise mechanisms, these findings suggest that infection of the immunologically immature fetus may lead in some cases to complete or partial antigen-specific unresponsiveness that may persist for some time after birth.

At least some neonates and young infants with congenital *T. gondii* infection show increased expansion of the Vγ2Vδ2-bearing γδ T-cell population, most of which express a $CD45RA^{lo}CD45RO^{hi}$ surface phenotype, indicating prior activation in vivo [808]. An analysis of a few patients found that αβ T cells in congenitally infected neonates show a poor proliferative response to stimulation by peripheral BMCs infected with viable or irradiated *T. gondii* organisms [808]. Other functions, such as the secretion of cytokines by these cells, were not assessed, and rigorous age-matched controls were not employed. These results suggest, however, that αβ T cells in infants with congenital toxoplasmosis may be anergic.

Although the foregoing results suggest that multiple aspects of cell-mediated immunity against *T. gondii* organisms are compromised in the human fetus and neonate, particularly in early gestation, antigen-specific antibody responses to *T. gondii* are commonly detectable (see Chapter 31 for more details). Antibodies to the P30 *T. gondii* antigen are frequently detectable in the fetus and neonate after congenital infection and are useful for serodiagnosis. Anti-P30 IgA antibodies are found in most neonates after congenital infection, whereas anti-P30 IgM antibodies are found in a few [1194,1228]. *T. gondii*–specific IgE antibodies may also be demonstrable within the first 2 months of life in congenitally infected infants [1229]. Anti-P30 IgA and IgE antibodies are not unique to the fetus and neonate, but also are common in older individuals with acquired toxoplasmosis. Together, these results suggest that isotype switching of antibodies from IgM to the IgA and IgE isotypes can occur in utero, particularly in the face of continuing antigenic stimulation. Because IL-4 produced by $CD4^+$ T cells is likely to be required for the production of protein antigen-specific IgE antibodies, these results suggest that the $CD4^+$ T-cell response to *T. gondii* organisms in the fetus may include the production of IL-4.

## Implications for Immunologic Intervention

The findings in human neonates, in concert with the results of studies in rodents, suggest that correction of the deficits in NK-cell function, cytokine production, and T-cell responses could facilitate treatment of infections with intracellular pathogens, such as *T. gondii*. Several limitations are apparent, however. Treatment of neonatal rats with IFN-γ after infection with *L. monocytogenes* is established is ineffective, whereas concomitant therapy or pretreatment is effective [1230]. In the case of congenital infection with *T. gondii*, therapy would need to be initiated and maintained in utero, when maternal infection is often asymptomatic, and there is no obvious way by which this could be safely targeted to the fetus. Data in mouse models suggest that increased production of IFN-γ during maternal infection may contribute to fetal loss as a result of maternal rejection of the fetus as a foreign allograft [1231]. After birth, it may be possible to provide exogenous IFN-γ (or perhaps TNF-α, IL-12, or IL-15), but the same caveats noted for treatment in cases of viral infection would apply. There are at present no safe and effective vaccines against *T. gondii*, and none is likely to be available in the near future [1232].

CHAPTER 5

# HUMAN MILK*

**Christopher B. Wilson** ✪ **Pearay L. Ogra**

## CHAPTER OUTLINE

Mother's milk delivered naturally through breast-feeding has been the sole source of infant nutrition in mammalian species for millions of years. Since human beings learned to domesticate cattle about 10,000 years ago, nonhuman mammalian milk also has been used to supplement or replace maternal milk in human infants. The development and widespread use of commercially prepared infant formula products have been phenomena of the 20th century and notably of the past 6 decades. Such products provide an alternative to breast-feeding that is useful in certain situations. Nonetheless, compelling evidence shows that breast-feeding is an ideal source of infant nutrition, whose use is associated with lower rates of postneonatal infant mortality in the United States and in other parts of the world [1–3]. Human milk helps to protect infants against a wide variety of infections; helps to reduce the risk for allergic and autoimmune diseases, the risk of obesity and its complications, and the risk for certain types of neoplasms later in life; and has been associated with slightly better performances on tests of cognitive development in some studies [3]. For these reasons, the American Academy of Pediatrics (AAP) and the World Health Organization (WHO) recommend that in the absence of specific contraindications (see "Benefits and Risks of Human Milk"), healthy term infants should be exclusively breast-fed or fed expressed breast milk beginning within the first hour after birth through 6 months of age [1,3].

* This chapter is rededicated to Lars A. Hansen, MD, PhD, the discoverer of sIgA in human milk, the father of modern "mother's milk feeding practices," and a remarkable human being.

DOI: 10.1016/B978-1-4160-6400-8.00005-5

Over the past few decades, the immune responses at intestinal and respiratory mucosal surfaces to local infections have been intensely studied. These investigations have led to the development of concepts of immunity on mucosal surfaces of gastrointestinal, respiratory, and genitourinary tracts and identification of mucosa-associated lymphoid tissue and local mechanisms of defense that are distinct from the internal (systemic) immune system. This chapter reviews existing information on major aspects of the physiologic, nutritional, immunologic, and anti-infective components of the products of lactation. Evidence on the contribution of human milk to the development of immunologic integrity in the infant and its influence on the outcome of infections and other host-antigen interactions is also discussed.

# PHYSIOLOGY OF LACTATION

## DEVELOPMENTAL ANATOMY OF THE MAMMARY GLAND

The rudimentary mammary tissue undergoes several developmental changes during morphogenesis and lactogenesis: In the 4-mm human embryo, the breast tissue appears as a tiny mammary band on the chest wall [4,5]; by the 7-mm embryonic stage, the mammary band develops into the mammary line, along which eventually develops the true mammary anlage; by the 12-mm stage, a primitive epithelial nodule develops; by the 30-mm stage, the primitive mammary bud appears. These initial phases of development occur in both genders (Table 5–1). Further development in the male apparently is limited, however, by androgenic or other male-associated substances [6,7]. Castration in male rat embryos early in gestation leads to female breast development, whereas ovariectomy in female rat embryos does not alter the course of development of the mammary anlage. Toward the end of pregnancy, initial phases of fetal mammary differentiation seem to occur under the influence of placental and transplacentally acquired maternal hormones, with transient development of the excretory and lactiferous ductular systems. Such growth, differentiation, and secretory activities are transient and regress soon after birth [7,8].

At thelarche, and later on at menarche, true mammary growth and development begin in association with rapidly increasing levels of estrogens, progesterone, growth hormone, insulin, adrenocorticosteroids, and prolactin [8,9]. Estrogens seem to be important for the growth and development of the ductular system, and progestins apparently are important for lobuloalveolar development (see Table 5–1). Final differentiation of the breast associated with growth and proliferation of the acinar lobes and alveoli continues to be influenced by the levels of estrogen and progesterone. Other peptide hormones, such as prolactin, insulin, and placental chorionic somatomammotropin, appear to be far more important for the subsequent induction and maintenance of lactation (see Table 5–1).

Prolactin secretion from the pituitary gland seems to be under neural control, and the increasing innervation of the breast observed throughout pregnancy apparently is regulated by estrogens [9]. Intense neural input in virgin and parturient, but not in currently pregnant, mammals has been shown to result in lactation. Lactation in goats can be induced by milking maneuvers. Adoptive breastfeeding also is well documented in primitive human societies. Sudden and permanent cessation of suckling can result in the termination of milk secretion and involution of the breast to the prepregnant state as the concentrations of prolactin decline. Estrogen and progesterone also may amplify the direct effects of prolactin or may induce additional receptors for this peptide hormone on appropriate target tissues in the breast.

## ENDOCRINE CONTROL OF MAMMARY GLAND FUNCTION

Breast tissue is responsive to hormones, even as a rudimentary structure, as illustrated by the secretion of "witch's milk" by male and female newborns in response to exposure to maternal secretion of placental lactogen, estrogens, and progesterone [5]. The secretion of this early milk ceases after exposure to maternal hormones has waned. Sexual differentiation, marked by puberty, is the next major stage in mammary development. As pointed out earlier, androgens inhibit the development of mammary tissue in males, whereas the development of mammary tissue in females depends on estrogen, progesterone, and pituitary hormones [10]. The postpubertal mammary gland undergoes cyclical changes in response to the release of hormones that occurs during the menstrual cycle. The last stage of development occurs during menopause, when the decline in estrogen secretion results in some atrophy of mammary tissue.

During the menstrual cycle, the mammary gland responds to the sequential release of estrogen and progesterone with a hyperplasia of the ductal system that

**TABLE 5–1** Possible Endocrine Factors in Growth of Human Female Mammary Glands

| Clinical State | Growth Characteristics | Maturational Hormones |
|---|---|---|
| Prenatal | Rudimentary | None |
| Infancy | Rudimentary | None |
| Puberty | Growth and budding of milk ducts | Growth hormone, prolactin-estrogen, corticosteroids, prolactin (high doses) |
| Pregnancy | Growth of acinar lobules and alveoli | Estrogen, progesterone, prolactin, growth hormone, corticosteroids |
| Parturition | Alveolar growth | Prolactin, corticosteroids |
| Lactational growth of tissue | None | None |
| Secretory products | Casein, α-lactalbumin | Prolactin, insulin, corticosteroids |

continues through the secretory phase and declines with the onset of menstruation. The concentration of prolactin modestly increases during the follicular stage of the menstrual cycle, but remains constant during the secretory phase [11]. Prolactin secretion seems to be held in readiness for the induction and maintenance of lactation.

## Initiation and Maintenance of Lactation

Pregnancy is marked by profound hormonal changes reflecting major secretory contributions from the placenta, the hypothalamus, and the pituitary gland, with contributions from many other endocrine glands (e.g., pancreas, thyroid, and parathyroid). Increased estrogen and progesterone levels during pregnancy stimulate secretion of prolactin from the pituitary, whereas placental lactogen seems to inhibit the release of a prolactin-inhibiting factor from the hypothalamus. Prolactin, lactogen, estrogen, and progesterone all aid in preparing the mammary gland for lactation. Initially in gestation, an increased growth of ductule and alveolobular tissue occurs in response to estrogen and progesterone. In the beginning of the second trimester, secretory material begins to appear in the luminal cells. By the middle of the second trimester, mammary development has proceeded sufficiently to permit lactation to occur should parturition take place.

When the infant is delivered, a major regulatory factor, the placenta, is lost, and new regulatory factors including the maternal-infant interaction and neuroendocrine regulation are gained for control of lactation. Loss of placental hormone secretion results in an endocrine hypothalamic stimulation of prolactin release from the anterior pituitary gland and neural stimulation of oxytocin from the posterior pituitary. The stimulation of the nipple by suckling activates a neural pathway that results in release of prolactin and oxytocin. Prolactin is responsible for stimulating milk production, whereas oxytocin stimulates milk ejection (the combination is known as the let-down reflex). Oxytocin also stimulates uterine contractions, which the mother may feel while she is breast-feeding; this response helps to restore the uterus to prepregnancy tone. Milk production and ejection depend on the complex interaction of stimulation by the infant's suckling, neural reflex of the hypothalamus to such stimulation, release of hormones from the anterior and posterior pituitary, and response of the mammary gland to these hormones to complete the cycle.

## Milk Secretion

Milk is produced as the result of synthetic mechanisms within the mammary gland and the transport of components from blood. Milk-specific proteins are synthesized in the mammary secretory cells, packaged in secretory vesicles, and exocytosed into the alveolar lumen. Lactose is secreted into the milk in a similar manner, whereas many monovalent ions, such as sodium, potassium, and chloride, depend on active transport systems based on sodium-potassium adenosine triphosphatases ($Na^+$,$K^+$-ATPases). In some situations, the mammary epithelium, which may behave as a "mammary barrier" between interstitial fluid derived from blood and the milk because of the lack of space between these cells, may "leak," permitting direct diffusion of components into the milk. This barrier results in the formation of different pools or compartments of milk components within the mammary gland and is responsible for maintaining gradients of these components from the blood to the milk.

Lipid droplets can be observed within the secretory cells of the mammary gland and are surrounded by a milk fat globule membrane. These fat droplets seem to fuse with the apical membrane of the secretory cells and to be exocytosed or "pinched off" into the milk [10]. Some whole cells also are found in milk, including leukocytes, macrophages, lymphocytes, and broken or shed mammary epithelial cells. The mechanisms by which these cells enter the milk are complex and include, among others, specific cellular receptor-mediated homing of antigen-specific lymphocytes.

As the structure of the mammary gland is compartmentalized, so is the structure of milk. The gross composition of milk consists of cytoplasm encased by cellular membranes in milk fat globule membranes (fat compartments composed of fat droplets), a soluble compartment containing water-soluble constituents, a casein-micelle compartment containing acid-precipitable proteins with calcium and lactose, and a cellular compartment. The relative amounts of these components change during the course of lactation, generally with less fat and more protein in early lactation than in late lactation. The infant consumes a dynamic complex solution that has physical properties permitting unique separation of different functional constituents from one another, presumably in forms that best support growth and development.

## Lactation Performance

Successful lactation performance depends on continued effective contributions from the neural, endocrine, and maternal-infant interactions that were initiated at the time of delivery. The part of this complex behavior most liable to inhibition is the mother-child interaction. Early and frequent attachment of the infant to the breast is mandatory to stimulate the neural pathways essential to maintaining prolactin and oxytocin release.

A healthy newborn infant placed between the mother's breasts locates a nipple and begins to suck spontaneously within the first hour of birth [12]. This rapid attachment to the mother may reflect olfactory stimuli from the breast received by the infant at birth [13]. Frequent feedings are necessary for the mother to maintain an appropriate level of milk production for the infant's proper growth and development. Programs to support lactation performance must emphasize proper maternal-infant bonding, relaxation of the mother, support for the mother, technical assistance to initiate breast-feeding properly and to cope with problems, and reduction of environmental hindrances. Such hindrances may include lack of rooming-in in the hospital, use of supplemental formula feeds, and lack of convenient day care for working mothers.

Lactation ceases when suckling stops; any behavior that reduces the amount of suckling by the infant initiates weaning or the end of lactation. Introduction of water in bottles or of one or two bottles of formula a day may begin the weaning process regardless of the time after parturition, but can be most damaging to the process when the mother-infant dyad is first establishing lactation.

## SECRETORY PRODUCTS OF LACTATION: NUTRITIONAL COMPONENTS OF HUMAN COLOSTRUM AND MILK

Colostrum and milk contain a rich diversity of nutrients, including electrolytes, vitamins, minerals, and trace metals; nitrogenous products; enzymes; and immunologically specific cellular and soluble products. The distribution and relative content of various nutritional substances found in human milk are presented in Table 5–2. The chemical composition often exhibits considerable variation among lactating women and in the same woman at different times of lactation [14], and between samples obtained from mothers of infants with low birth weight and from mothers of full-term infants [15,16]. Mature milk contains the following average amounts of major chemical constituents per deciliter: total solids, 11.3 g; fat, 3 g; protein, 0.9 g; whey protein nitrogen, 760 mg; casein nitrogen, 410 mg; α-lactalbumin, 150 mg; serum albumin, 50 mg; lactose, 7.2 g; lactoferrin, 150 mg; and lysozyme, 50 mg.

Human milk contains relatively low amounts of vitamins D and E (see Table 5–2) and little or no β-lactoglobulin (the major whey protein in bovine milk). The fat globule membrane seems to have a high content of oleic acid, linoleic acid, phosphatidylpeptides, and inositol [17]. In addition, a binding ligand that promotes absorption of zinc has been identified in human milk [18,19]. Temporal studies have indicated that concentrations of many chemical components, especially nitrogen, calcium, and sodium, decrease significantly as the duration of lactation increases [20,21]. Several components have been found to change in concentration as a function of water content, however, because their total daily output seems to be remarkably constant, at least during the first 8 weeks of lactation [22,23].

Milk production progresses through three distinct phases, characterized by the secretion of colostrum, transitional (early) milk, and mature milk. Colostrum comprises lactational products detected just before and for the first 3 to 4 days of lactation. It consists of yellowish, thick fluid, with a mean energy value of greater than 66 kcal/dL and contains high concentrations of immunoglobulin, protein, fat, fat-soluble vitamins, and ash. Transitional milk usually is produced between days 5 and 14 of lactation, and mature milk is produced thereafter. The concentrations of many nutritional components decline as milk production progresses to synthesis of mature milk. The content of fat-soluble vitamins and proteins decreases as the water content of milk increases. Conversely, levels of lactose, fat, and water-soluble vitamins and total caloric content have been shown to increase as lactation matures [24,25].

As the result of several manufacturing errors, the nutrient composition of infant formulas has been legislated [26], resulting in the paradoxical situation that human milk may not always meet the recommended standards for some nutrients, whereas infant formulas may exceed the recommendation. Human milk nutrient composition varies with time of lactation (colostrum versus early milk versus mature milk) and, to some extent, maternal nutritional status. The appropriate amounts of each nutrient must be considered within these constraints.

**TABLE 5–2** Distribution of Secretory Products in Human Colostrum and Milk*

| | |
|---|---|
| Water | 86%-87.5% |
| Total Solids | 11.5 g |
| ***Nutritional Components*** | |
| Lactose | 6.9-7.2 g |
| Fat | 3-4.4 g |
| Protein | 0.9-1.03 g |
| α-lactalbumin | 150-170 mg |
| β-lactoglobulin | Trace |
| Serum albumin | 50 mg |
| ***Electrolytes, Minerals, Trace Metals*** | |
| Sodium | 15-17.5 mg |
| Potassium | 51-55 mg |
| Calcium | 32-43 mg |
| Phosphorus | 14-15 mg |
| Chloride | 38-40 mg |
| Magnesium | 3 mg |
| Iron | 0.03 mg |
| Zinc | 0.17 mg |
| Copper | 15-105 μg |
| Iodine | 4.5 μg |
| Manganese | 1.5-2.4 μg |
| Fluoride | 5-25 μg |
| Selenium | 1.8-3.2 μg |
| Boron | 8-10 μg |
| | Total 0.15-2 g |
| ***Nitrogen Products*** | |
| Whey protein nitrogen | 75-78 mg |
| Casein protein nitrogen | 38-41 mg |
| Nonprotein nitrogen | 25% of total nitrogen |
| Urea | 0.027 g |
| Creatinine | 0.021 g |
| Glucosamine | 0.112 g |
| ***Vitamins*** | |
| C | 4.5-5.5 mg |
| Thiamine (B1) | 12-15 μg |
| Niacin | 183.7 μg |
| B6 | 11-14 μg |
| B12 | <0.05 μg |
| Biotin | 0.6-0.9 μg |
| Folic acid | 4.1-5.2 μg |
| Choline | 8-9 mg |
| Inositol | 40-46 mg |
| Pantothenic acid | 200-240 μg |
| A (retinol) | 54-56 μg |
| D | <0.42 IU |
| E | 0.56 μg |
| K | 1.5 μg |

**Estimates based on amount per deciliter.*

## Minerals

The mineral content of human milk is low relative to that of infant formulas and very low compared with cow's milk, from which most formulas are prepared; although human milk is sufficient to support growth and development, it also represents a fairly low solute load to the developing kidney. The levels of major minerals tend to decline during lactation, with the exception of magnesium, but with considerable variability among women tested [27]. Sodium, potassium, chloride, calcium, zinc, and phosphorus all seem to be more bioavailable in human milk than in infant formulas, reflecting their lower concentrations in human milk. Iron is readily bioavailable to the infant from human milk, but may have to be supplemented later in lactation [28,29]. Preterm infants fed human milk may need supplements of calcium and sodium [30].

## Vitamins

Human milk contains sufficient vitamins to maintain infant growth and development, with the caveat that water-soluble vitamins are particularly dependent on maternal intake of these nutrients [31]. Preterm infants may require supplements of vitamins D, E, and K when fed human milk [32,33]. The low content of vitamin D in human milk has been related to the development of rickets in a few breast-fed infants, as discussed later [34]. The AAP currently recommends that all breast-fed infants receive 200 IU of oral vitamin D drops daily beginning in the first 2 months of life and continuing until adequate amounts of vitamin D are provided through daily consumption by the infant of fortified formula or milk [3].

## Carbohydrates and Energy

Lactose is the primary sugar found in human milk and usually is the carbohydrate chosen for the preparation of commercial formulas. Lactose supplies approximately half the energy (of a total 67 kcal/dL) taken in by the infant from human milk. Lactose (a disaccharide of glucose and galactose) also may be important to the neonate as a carrier of galactose, which may be more readily incorporated into gangliosides in the central nervous system than galactose derived from glucose in the neonate [35]. Also, glycogen may be synthesized more efficiently from galactose than from glucose in the neonate because of the relatively low activity of glucokinase in early development [36]. Human milk also contains other sugars, including glucose and galactose and more than 100 different oligosaccharides [37]. These oligosaccharides may have protective functions for the infant, especially with respect to their ability to bind to gastrointestinal pathogens [38].

## Lipids

Fats provide almost half of the calories in human milk, primarily in the form of triacylglycerols (triglycerides) [33]. These lipids are supplied in the form of fat globules enclosed in plasma membranes derived from the mammary epithelial cells [39]. The essential fatty acid linoleic acid supplies about 10% of the calories derived from the lipid fraction. Triacylglycerols serve as precursors for prostaglandins, steroids, and phospholipids and as carriers for fat-soluble vitamins. The lipid profiles of human milk differ dramatically from the lipid profiles of commercial formulas, and despite considerable adaptation of such formulas, human milk lipids are absorbed more efficiently by the infant.

Cholesterol, an important lipid constituent of human milk (12 mg/dL), usually is found in only trace amounts in commercial formulas. It has been suggested that cholesterol may be an essential nutrient for the neonate [40]. A lack of cholesterol in early development may result in turning on of cholesterol-synthetic mechanisms that are difficult to turn off later in life, influencing induction of hypercholesterolemia [41]. Some studies suggest that breast-feeding of the neonate is associated with lowered adult serum cholesterol levels and reduced deaths from ischemic heart disease [42].

Interest has increased in the role that long-chain polyunsaturated fatty acids may play in human milk, especially docosahexaenoic acid and arachidonic acid. These long-chain polyunsaturated fatty acids are not found in unsupplemented infant formulas, but are present in human milk. They are structural components of brain and retinal membranes and may be important for cognitive and visual development. In addition, they may have a role in preventing atopy [43]. Numerous studies have found that infants fed formula without docosahexaenoic acid or arachidonic acid have reduced red blood cell amounts of these fatty acids [44–46]; however, findings in visual and cognitive functional studies in term infants have been inconsistent [47,48]. These studies have been complicated by the finding of slower growth in some preterm infants fed formulas supplemented with long-chain polyunsaturated fatty acids [45,46]. The inconsistent findings in infants fed supplemented formula may reflect the difficulty in determining the optimal amounts of docosahexaenoic acid and arachidonic acid and their precursors linoleic and linolenic acids in such supplemented formulas. These lipids seem to be best delivered from human milk.

## Protein and Nonprotein Nitrogen

The exact protein content of mature human milk is variable, but is around 1 g/dL, in contrast to infant formulas, which usually contain 1.5 g/dL; the milk from mothers who deliver preterm infants may have slightly more protein [49]. The nutritionally available protein may be less than 1 g/dL—possibly 0.8 g/dL—as a result of the proportion of proteins that is used for non-nutritional purposes. In addition, human milk contains a considerably greater percentage of nonprotein nitrogen (25% of the total nitrogen) compared with formulas (5% of the total nitrogen) [50].

Human milk protein is primarily whey predominant (acid-soluble protein), whereas formulas prepared from bovine milk classically reflect the 18% whey–82% casein protein composition in that species. The whey-to-casein protein ratio in humans may change during lactation, with the whey component ranging from 90% (early milk) to 60% (mature milk) to 50% (late milk) [51]. Formulas for preterm infants have been reconstituted from bovine milk to provide 60% whey and 40% casein proteins; all major formulas for term infants in the United States are

now bovine whey-protein–predominant preparations, in an attempt to make them closer to human milk in composition. These differences in protein quality are reflected by differences in the plasma and urine amino acid responses of infants fed human milk or formulas that are casein-protein–predominant or whey-protein–predominant [52–54]. Generally, term infants do not respond with the dramatic differences seen in preterm infants when fed formulas with different protein quality [55–58].

The nonprotein nitrogen component of human milk contains various compounds that may be important to the development of the neonate: polyamines, nucleotides, creatinine, urea, free amino acids, carnitine, and taurine [59]. The significance of the presence of these components is not always clear, but when they are not fed, as in the case of infant formulas that contain little taurine [52] or of soy formulas that contain little carnitine [60], apparent deficiencies that may influence the development of the infant occur. Taurine is important for bile salt conjugation and for support of appropriate development of the brain and retina [40], whereas carnitine seems to be important for appropriate fatty acid metabolism [61].

Nucleotides, in particular, seem to bridge the gap between the nutritional and the immunologic roles of human milk components. Human milk contains most of these compounds in the form of polymeric nucleotides or nucleic acids [62,63], whereas formulas contain nucleotides (when they are supplemented) only in the monomeric forms (Table 5–3). Nucleotides seem to enhance intestinal development, promote iron absorption, and modify lipid metabolism in their nutritional role [64]. These compounds perform an immunologic function by promoting killer cell cytotoxicity and interleukin (IL)-2 production by stimulated mononuclear cells from infants either breast-fed or fed nucleotide-supplemented formulas [65].

Nucleotide supplementation also has been reported to reduce the number of episodes of infant diarrhea in a group of infants of lower socioeconomic status in Chile, in a manner analogous to that for protection afforded by human milk [66]. In 1998, it was reported that nucleotide-supplemented formulas promoted the immune response of infants to *Haemophilus influenzae* type b polysaccharide immunization at 7 months of age, and a similar response was observed for diphtheria immunization [67]. Infants fed human milk for more than 6 months showed a similar response and exhibited an enhanced titer response to oral polio vaccine; this latter response was not observed in the group fed nucleotide-supplemented formula [67]. Nucleotides are emerging as nutritional and immunologic components of human milk.

**TABLE 5–3** Nucleotides in Human Milk and Supplemented Formula

| | Human Milk* | Human Milk† | Formula* |
|---|---|---|---|
| Nucleic acid (%) | 48 | 42 | 4 |
| Nucleotides (%) | 36 | 52 | 81 |
| Nucleosides (%) | 8 | 7 | 15 |
| Total (μmol/L) | 402 | 163 | 141 |

## Nutritional Proteins

As noted, the nutritional proteins in human milk are classified as either whey (acid-soluble) or casein (acid-precipitable). Within these two classes of proteins, several specific proteins are responsible for supporting the nutritional needs of the infant.

Human casein is composed primarily of β-casein and κ-casein, although the actual distribution of these two proteins is unclear [68]. By contrast, bovine milk contains $\alpha_{s1}$-casein and $\alpha_{s2}$-casein (neither of which is found in human milk), in addition to β-casein and κ-casein [69]. These two human milk casein proteins seem to account for approximately 30% of the protein found in human milk, in contrast to the earlier calculation of 40% (the amount commonly used to prepare reconstituted, so-called humanized formulas from bovine milk, which normally contains 82% casein proteins).

The whey-protein fraction contains all of the proposed functional proteins in human milk (immunoglobulins, lysozyme, lactoferrin, enzymes, cytokines, peptide hormones), in addition to the major nutritional protein, α-lactalbumin. Whey proteins compose approximately 70% of human milk proteins, in contrast to 18% in bovine milk. Although α-lactalbumin is the major whey protein in human milk, β-lactoglobulin is the major whey protein in bovine milk (and is not found in human milk) [50]. A consistent fraction of human milk whey protein is composed of serum albumin. Its source is unclear; some evidence indicates that it may be synthesized in the mammary gland [70]. Most of the serum albumin probably is synthesized outside the mammary gland, however.

Milk proteins are characterized by their site of synthesis and are species specific. Proteins such as α-lactalbumin and β-lactoglobulin are species and organ specific, whereas proteins such as serum albumin are species specific, but not organ specific [71]. The net result of these differences in proteins used for nutrition by the neonate is that different amounts of amino acids are ingested by the neonate, depending on the source of milk; even reconstitution of the whey and casein classes of proteins from one species in a ratio similar to that of another species does not result in an identical amino acid intake. These differences are reflected in plasma amino acid profiles of infants fed commercial milks versus human milk, regardless of the ratios of reconstitution [54].

## Bioactive Proteins and Peptides

Although a major proportion of human milk protein is composed of the nutritional proteins just described, many of the remaining proteins subserve a variety of functions, other than or in addition to the nutritional support of the neonate. These proteins include carrier proteins, enzymes, hormones, growth factors, immunoglobulins, and cytokines (the latter two are discussed later in "Resistance to Infection"). Whether these proteins are still functional after they have been ingested by the neonate has not always been established, but it is clear that human

milk supplies a mixture that is potentially far more complex than just nutritional substrate.

### Carrier Proteins

Many nutrients are supplied to the neonate bound to proteins found in human milk. This binding may play an important role in making these nutrients bioavailable. Lactoferrin is an iron-binding protein (a property that also may play a role in its bacteriostatic action) that is apparently absorbed intact by the infant [72]. Lactoferrin may be important in the improved absorption of iron by the infant from human milk compared with iron from cow's milk preparations, which contain little lactoferrin [28]. Lactoferrin also may bind other minerals, including zinc and manganese, although the preferred mineral form seems to be the ferric ion.

Numerous other proteins seem to be important as carriers of vitamins and hormones. Folate-binding, vitamin $B_{12}$–binding, and vitamin D–binding proteins all have been identified in human milk. These proteins apparently have some resistance to proteolysis, especially when they are saturated with the appropriate vitamin ligand [73]. Serum albumin acts as a carrier of numerous ligands, whereas α-lactalbumin acts as a carrier for calcium. Finally, proteins that bind thyroid hormone and corticosteroids have been reported to be present in human milk [74,75], although serum albumin may partially fulfill this function.

### Enzymes

The activity of more than 30 enzymes has been detected in human milk [76]. Most of these enzymes seem to originate from the blood, with a few originating from secretory epithelial cells of the mammary gland. Little is known about the role of these enzymes, other than lysozyme and the lipases, in human milk. The enzymes found in human milk range from ATPases to antioxidant enzymes, such as catalase, to phosphatases and glycolytic enzymes. Although these enzymes have important roles in normal body metabolism, it is unclear how many of them either function in the milk itself or survive ingestion by the neonate to function in the neonate.

Lysozyme seems to have a part in the antibacterial function of human milk, whereas the lipases have a more nutrient-related role in modulating fat metabolism for the neonate. Two lipases have been identified in human milk: a lipoprotein lipase and a bile salt–stimulated lipase [77]. Lipoprotein lipase seem to be involved in determining the pattern of lipids found in human milk by regulating uptake into milk at the level of the mammary gland. Human milk bile salt–stimulated lipase is an acid-stable protein that compensates for the low activity of lipases secreted into the digestive tract during early development [78]. These two enzymes regulate the amount and the pattern of lipid that appears in milk and the extremely efficient absorption of lipid by the infant. Human milk lipid is absorbed much more readily than lipid from commercial milk formulas despite the many adaptations that have been made to improve absorption, illustrating the effective mechanisms supported by the lipases.

### Hormones and Growth Factors

Peptide, steroid hormones, and growth factors have been identified in trace amounts in human milk, although as with most enzymes, it is unclear to what degree they function in the neonate who has ingested the milk. As discussed previously, binding proteins for corticosteroids and thyroxine have been identified in milk and, by extrapolation from observations of other milk components, may play a role in making these bioactive compounds more readily available to the infant.

Among the hormones identified in human milk are insulin, oxytocin, calcitonin, and prolactin. Most of these hormones apparently are absorbed by the infant, but their role in in vivo function is unclear [79]. Breast-fed infants seem to have a different endocrine response from that of formula-fed infants, presumably reflecting the intake of hormones from human milk [80]. The advantages or disadvantages to the infant of these responses are unknown.

Human milk also contains a rich mixture of growth factors, including epidermal growth factor, nerve growth factor, and transforming growth factor-β [81]. In addition, various gastrointestinal peptides have been identified in human milk. Presumably, the supply of these various factors to the infant through milk compensates for their possible deficiency in the infant during early development.

The composition of human milk provides a complex and complete nutritional substrate to the neonate. Human milk supplies not only individual nutrients, but also enzymes involved in metabolism, carriers to improve absorption, and hormones that may regulate metabolic rates. Commercial formulas have not yet been developed to the point that they can provide an analogous complete nutritional system.

## Special Considerations for the Premature Neonate

Many of the benefits of human milk evident in term neonates are also evident in preterm neonates with very low birth weight (<1500 g) fed unfortified human milk; the incidence of necrotizing enterocolitis also seems to be reduced [82–84]. Nonetheless, the content of calcium, phosphorus, protein, sodium, vitamins, and energy in unfortified human milk may be inadequate to meet the needs of the very low birth weight preterm neonate, and if used as an exclusive source of nutrients, unfortified human milk may be associated with impaired growth and nutrient deficiencies. Meta-analysis of studies comparing these premature infants fed unfortified or fortified human milk found that fortified milk was associated with greater increases in weight, length, and head circumference and better nitrogen balance and bone mineral content without an increase in feeding intolerance or complications [83,85].

The feeding of fortified human milk does not seem to be associated with a substantially increased rate of feeding intolerance or with a reduction in the beneficial effects of human milk on rates of infections or necrotizing enterocolitis [84]. The quality of the data regarding the utility of fortified human milk is still limited, however, and additional research is needed to define better means by which to provide the benefits of human milk to these preterm infants, while meeting their specific nutritional requirements.

# RESISTANCE TO INFECTION

## COMPONENT MECHANISMS OF DEFENSE: ORIGIN AND DISTRIBUTION

Fresh human milk contains a wealth of components that provide specific and nonspecific defenses against infectious agents and environmental macromolecules (Table 5–4). These component factors include cells such as T and B lymphocytes, polymorphonuclear neutrophils (i.e., polymorphonuclear leukocytes), and macrophages; soluble products, especially immunoglobulins; secretory immunoglobulin A (sIgA); immunomodulatory cytokines and cytokine receptors; components of the complement system; several carrier proteins; enzymes; and numerous endocrine hormones or hormone-like substances. Additional soluble factors that are active against streptococci, staphylococci, and tumor viruses also have been identified [24,86]. Epidermal growth factor promotes growth of mucosal epithelium and maturation of intestinal brush border.

The developmental characteristics of sIgA have been studied more extensively than those of other components [87–89]. On the basis of available information, most IgA-producing cells observed in milk have their origin in the precursor immunocompetent cells in the gut-associated lymphoid tissue (GALT) and bronchus-associated lymphoid tissue (BALT). Exposure of IgA precursor B lymphocytes in GALT or BALT to microbial and dietary antigens in the mucosal lumen is an important prerequisite for their initial activation and proliferation. Such antigen-sensitized cells eventually are transported through the systemic circulation to other mucosal surfaces, including the mammary glands, and, as plasma cells, initiate the synthesis of immunoglobulin against specific antigens previously experienced in the mucosa of the respiratory or alimentary tract [87]. It has been proposed that T cells observed in the milk also may be derived from GALT and BALT in a manner similar to that of IgA-producing cells. Little or no information is available regarding the site of origin of other cellular or soluble immunologic components normally present in human milk. Specific antibody and cellular immune reactivity against many respiratory and enteric bacterial and viral pathogens and ingested food proteins also is present in human breast milk (Table 5–5).

## SOLUBLE PRODUCTS

### IgA

As observed in other peripheral mucosal sites, the major class of immunoglobulin in human colostrum and milk is 11S sIgA. Other isotypes—7S IgA, IgG, IgM, IgD, and IgE—also are present. The 11S IgA exists as a dimer of two 7S IgA molecules linked together by a polypeptide chain, the J-chain, and is associated with a nonimmunoglobulin protein referred to as the secretory component. The sIgA protein constitutes about 75% of the total nitrogen content of human milk. The IgA dimers produced by plasma cells at the basal surface of the mammary epithelium are bound by the polymeric immunoglobulin receptor on the basolateral surface of mammary epithelial cells, which transports them through these cells, where they are released into the alveolar spaces as an 11S IgA dimer associated with a portion of the polymeric immunoglobulin receptor referred to as the secretory component [90].

Sequential quantitation of class-specific immunoglobulin in human colostrum and milk has shown that the highest levels of sIgA and IgM are present during the first few days of lactation (Fig. 5–1). Levels of IgA are 4 to 5 times greater than levels of IgM, 20 to 30 times greater than levels of IgG, and 5 to 6 times greater than levels of serum IgA [89]. As lactation progresses, IgA declines to levels of 20 to 27 mg per gram of protein, and IgM levels decline to 3.5 to 4.1 mg/g protein. IgG levels do not show any significant change during early and late lactation and usually are maintained in the range of 1.4 to 4.9 mg/g protein (see Fig. 5–1). Although a dramatic and rapid decline in milk IgA and IgM occurs during the first week of life, this

Immunologic aspects of human colostrum and milk, II: characteristics of lymphocyte reactivity and distribution of E-rosette forming cells at different times after the onset of lactation. J Pediatr 92:550-555, 1978.)*

decrease is more than balanced by an increase in the volume of milk produced as the process of lactation becomes established (Table 5–6; see Fig. 5–1).

IgA antibodies found in milk possess specificity for infectious agents endemic to or pathogenic for the intestinal and respiratory tracts (see Table 5–4). These antibodies may be present in the milk in the absence of specific circulating IgA. In a study in which pregnant women were given oral feedings of *Escherichia coli* O83, development of IgA antibody in human milk was evident in the absence of detectable serum antibody-specific responses [91]. In another study, investigators observed similar responses in animal models using intrabronchial immunization with *Streptococcus pneumoniae*. These and other studies [92–95] have strongly supported the concept of a bronchomammary, and enteromammary, axis of immunologic reactivity in the breast.

Despite the elegance of studies that have defined the mechanisms of IgA cell trafficking from GALT and BALT to the mammary glands, the actual number of B cells or IgA plasma cells in the mammary glands is sparse. Colostrum and milk may contain large amounts of IgA (11 g in colostrum and 1 to 3 g per day in later milk), as shown in Table 5–6. The reasons underlying the apparent disparity between the content of immunoglobulin-producing cells and concentrations of immunoglobulin are unknown. The disparity may be related to the unique hormonal environment of the mammary glands. The hormones that have been consistently observed in human milk are listed in Table 5–4.

The effects of pregnancy-related and lactation-related hormones on regulation of immunologic reactivity present in the resting and lactating breast have been examined [96]. In a study of immunoglobulin production in the nonlactating human breast, several interesting findings were noted [97]. Few mononuclear cells were present in the nonlactating breast of nulliparous and of parous women, although IgA-containing cells predominated. Synthesis of IgA seemed to be slightly increased in the parous women. IgA was found in the mammary tissues during the proliferative stage of the menstrual cycle in the nulliparous women and during the luteal phase in the parous women. The number of IgA-producing cells in the nonlactating breast was observed to increase with

**TABLE 5–6** Level of Immunoglobulins in Colostrum and Milk and Estimates of Delivery of Lactational Immunoglobulins to the Breast-Feeding Neonate*

| | Percentage of Total Proteins Represented by Immunoglobulin | | | Output of Immunoglobulin (mg/24 hr) | | |
|---|---|---|---|---|---|---|
| **Day Postpartum** | **IgG** | **IgM** | **IgA** | **IgG** | **IgM** | **IgA** |

**Estimates based on the available data for total immunoglobulin and daily protein synthesis (see references 8, 87, and 88).*

parity. These findings suggest that the immunologic makeup of the nonlactating and the lactating breast may be significantly influenced by the hormonal milieu.

In another study of virgin mice given exogenously administered hormones [98], an extended exposure to estrogen, progesterone, and prolactin was necessary for maximal increments in IgA-producing plasma cells in the breast. Similarly, castrated males exposed to these hormones became moderately receptive to mammary gland homing of cells specific for IgA synthesis. As would be expected, testosterone eliminated female breast receptivity to these cells. These studies suggest the existence of a hormonally determined homing mechanism in the mammary gland for class-specific, immunoglobulin-producing cells.

More recent studies have proposed another possible influence of lactational hormones on immunocompetent cells. In limited observations, combinations of prolactin with estrogen and progesterone (in concentrations observed normally at the beginning of parturition) seemed to have an amplifying effect on the synthesis and secretion of IgA from peripheral blood lymphocytes [99]. This observation raises the possibility that the high levels of sIgA observed in colostrum and milk may be partly the result of selective, hormonally mediated proliferation of antigen-sensitized IgA cells in the peripheral blood. The immunoglobulin could acquire a secretory component during its passage through the mammary epithelium and eventually appear in the colostrum or milk as mature sIgA. Although the appearance of sIgA antibody in milk characteristically follows antigenic exposure in GALT or BALT, the precise nature of the IgA content in milk seems to be determined by various other factors operating in the mucosal lymphoid tissue. These factors include the dendritic cell and regulatory T-cell network in GALT and possibly in BALT [100,101], the nature of antigens (soluble proteins versus particulate microbial agents) [102], and the route of primary versus secondary antigenic exposure [103].

It has been estimated that the breast-fed infant may consistently receive about 1 g of IgA each day, and approximately 1% of this amount of IgM and IgG [104,105]. The estimates of lactational immunoglobulin delivered to the breast-fed infant at different periods of lactation are presented in Table 5–6. Most ingested IgA is eliminated in the feces, although 10% may be absorbed from the intestine into the circulation within the first 18 to 24 hours after birth [106]. Feces of breast-fed infants contain functional antibodies present in the ingested milk [107]. Other studies support the finding of prolonged survival of milk IgA in the gastrointestinal tract. Infants fed human milk have shown the presence of all immunoglobulin classes in the feces. Fecal IgA content was three to four times greater than that of IgM after human milk feeding. Comparative studies on survival of human milk IgA and bovine IgG in the neonatal intestinal tract have suggested that the fecal content of IgA may be 14 to 20 times greater after human milk feeding than that of bovine IgG after feeding of bovine immunoglobulin [108].

Endogenous production of sIgA by the infant's mucosal immune system increases progressively in the postnatal period [109]. Nonetheless, breast-fed infants have substantially greater concentrations of fecal sIgA than formula-fed infants. Prentice and colleagues [110] found approximately 10-fold and approximately 4-fold higher concentrations of sIgA in the stools of breast-fed infants compared with formula-fed infants at 6 and 12 weeks of postnatal age, even though only approximately 15% to 20% of ingested sIgA appeared in the feces.

Direct information about the role of milk IgA in antimicrobial defense is available in several studies. sIgA interferes with bacterial adherence to cell surfaces [111]. Colostrum and milk can inhibit the activity of *E. coli* and *Vibrio cholerae* enterotoxins in experimental settings [112]. The antitoxic activity of human milk seems to correlate well with its IgA content, but not with its IgM and IgG content. Precoating of *V. cholerae* with specific sIgA protects infant mice from disease [113]. Similar results have been obtained by using specific purified milk sIgA in preventing *E. coli*–induced and *Shigella dysenteriae*–induced disease in rabbits [114]. Less definite, but suggestive, is a study conducted with human milk feeding relative to the intestinal replication of orally administered live poliovirus vaccine [115]. This study found that breast-feeding may reduce the degree of seroconversion for poliovirus antibody in the vaccinated infants. Because antipolio IgA is present in human milk and colostrum, the investigators concluded that specific IgA may bind poliovirus and influence viral replication in the intestinal mucosa. Extensive experience with oral polio immunization worldwide has not found a convincing association, however, between breast-feeding and live vaccine failures. Other studies have shown that the magnitude of poliovirus

replication in the intestine is determined by the presence and level of preexisting sIgA antibody. With high levels of intestinal IgA antibody, little or no replication of vaccine virus was observed in the gut. With lower levels, varying degrees of viral replication could be shown [116].

Epidemiologic studies strongly support the notion that breast-feeding protects the infant against infectious diseases (see "Benefits and Risks of Human Milk"). It is impossible in these studies, however, to dissect the relative contribution of sIgA from the contributions of other soluble or cellular components present in colostrum and milk.

### IgG and IgM

Normal neonates exhibit characteristic paucity or lack of serum IgA and sIgA during the first 7 to 10 days after birth. At that time, the presence of IgM and IgG in milk may be important to compensate for immunologic functions not present in the mucosal sites. IgG and IgM participate in complement fixation and specific bactericidal activity, functions not associated with IgA. Studies done after oral feeding of immune serum globulin (mostly IgG) suggested that IgG may survive in the gastrointestinal tract of infants with low birth weight [117]. Other immunoglobulin isotypes in milk also may be able to serve as effective substitutes for IgA in the neonates of IgA-deficient mothers in prevention of infection with enteric or respiratory pathogens.

### IgE and IgD

Investigations have failed to show local synthesis of IgE in the breast [118–120]. Although IgE may be detected in 40% of colostrum and milk samples, the concentrations are extremely low, and many samples of colostrum and milk contain no IgE activity when paired samples of serum contain high IgE levels. IgD has been detected in most colostrum and milk samples. It has been suggested that nursing women with high serum IgD levels are more likely to have high IgD concentrations in their milk. The possibility of some local production of IgE and IgD cannot be ruled out [120].

## CELLULAR ELEMENTS

Human colostrum and milk contain lymphocytes, monocytes-macrophages, neutrophils, and epithelial cells [121]. Early colostrum contains the highest concentration of cells, approximately $1 \times 10^6$ to $3 \times 10^6$ cells/mL. By the end of the first week of lactation, cell concentration is of the order of $10^5$ cells/mL. Total cell numbers delivered to the newborn throughout lactation may remain constant, however, when adjustments are made for the increase in volume of milk produced [89]. The two major cell populations in human milk—macrophages and neutrophils—are difficult to distinguish by common staining methods because of numerous intracytoplasmic inclusions. More accurate estimates made by flow cytometry analysis suggest that the relative percentages of neutrophils, macrophages, and lymphocytes in early milk samples are approximately 80%, 15%, and 4% [122,123]. The remaining cells are present in smaller amounts, especially in the absence of active suckling, engorgement, or local breast infection.

### Macrophages

Histochemically, the milk macrophage differs from the blood monocyte in showing decreased peroxidase staining, with increased lysosomes and significant amounts of immunoglobulin, especially IgA, in the cytoplasm [124–126]. The intracellular immunoglobulin in macrophages represents 10% of milk IgA [127]. Kinetic studies on the release of IgA by human milk macrophages suggest that immunoglobulin release by macrophages, in contrast to immunoglobulin release by other phagocytic cells, is a time-dependent phenomenon and is not significantly influenced by the use of secretagogues or stimulants, such as phorbol myristate acetate [127]. Active phagocytosis is associated, however, with significant increase in release of IgA [128].

The precise functions of macrophages in colostrum or milk have not been fully explored. These cells have been suggested as potential transport vehicles for IgA [126,129]. Milk macrophages possess phagocytic activity against *Staphylococcus aureus*, *E. coli*, and *Candida albicans*, with possible cytocidal activity against the first two organisms [130]. Milk macrophages participate in antibody-dependent, cell-mediated cytotoxicity for herpes simplex virus type 1–infected cells [131]. Infection of milk macrophages by respiratory syncytial virus results in the production of the proinflammatory cytokines IL-1β, IL-6, and tumor necrosis factor (TNF)-α [132]. These cells also are involved in various other biosynthetic and excretory activities, including production of lactoferrin, lysozyme [133], components of complement [134], properdin factor B, epithelial growth factors, and T lymphocyte–suppressive factors [87]. Milk macrophages also have been suggested to be important in regulation of T-cell function [135,136].

### Lymphocytes

Milk contains a few lymphocytes; 80% are T cells, and 4% to 6% are B cells [123]. The small number of B cells reflects the sessile nature of these cells, which enter the lamina propria of the mammary gland to transform into plasma cells. Although several investigators have been unable to show in vitro antibody synthesis by milk lymphocytes, studies performed with colostral B cells transformed by Epstein-Barr virus showed production of IgG and J-chain–containing IgM and IgA [137]. A small population of $CD16^+$ natural killer (NK) cells also can be identified in most milk samples, but cannot be accurately quantitated [123]. In functional studies, colostral cells exhibit NK cytotoxicity, however, which is enhanced by interferon (IFN) and IL-2. Colostral cells also elicit antibody-dependent and lectin-dependent cellular cytotoxic responses. The NK and the antibody-dependent and lectin-dependent responses in colostral cells have been observed to be significantly lower than those of autologous peripheral blood cells. Reduced cellular cytotoxicity of colostral cells also has been observed against virus-infected targets and certain bacteria. With several specific virus-infected targets, colostrum and milk cells conspicuously lack cellular cytotoxicity compared with autologous peripheral blood cells. There is also an apparent exclusion of cytolytic T cells in the milk that are specific for certain human leukocyte antigens (HLA) [138,139].

**TABLE 5–7** Lymphocyte Subpopulations in Human Milk and Autologous Blood*

| Lymphocyte Subpopulation | Human Milk | Blood |
|---|---|---|
| CD3+† | 83 ± 11 | 75 ± 7 |
| CD3+ CD4+† | 36 ± 13 | 44 ± 6 |
| CD3+ CD8+† | 43 ± 12 | 27 ± 4 |
| CD4+/CD8+‡ | 0.88 ± 0.35 | 1.70 ± 0.45 |
| CD19+† | 6 ± 4 | 14 ± 5 |

*Expressed as mean ± standard deviation (SD).*
†*Expressed as percentage of total lymphocytes.*
‡*Ratio of $CD3^+/CD4^+$ to $CD3^+/CD8^+$ lymphocytes.*
*Adapted from Wirt DP, et al. Activated-memory T lymphocytes in human milk. Cytometry 13:282-290, 1992.*

Most T lymphocytes in colostrum and milk are mature $CD3^+$ cells. $CD4^+$ (helper) and $CD8^+$ (cytotoxic) populations are present in human milk, with a proportion of $CD8^+$ T cells higher than that found in human blood (Table 5–7). The $CD4^+/CD8^+$ ratio in milk is significantly lower than the ratio observed in peripheral blood and is not due to an increase of $CD8^+$ cells in the peripheral blood of women during the postpartum period. Colostral and milk T lymphocytes manifest in vitro proliferative responses on stimulation with numerous mitogens and antigens. Several studies have shown a selectivity in lymphocyte stimulation responses in colostral and milk lymphocytes to various antigens compared with peripheral blood lymphocyte responses [140,141]. Antigens such as rubella virus stimulate T lymphocytes in secretory sites and milk and in systemic sites [140]. By contrast, *E. coli* K1 antigen, whose exposure is limited to mucosal sites, produces stimulation of lymphoproliferative responses only in milk lymphocytes. These findings support the concept of select T-cell populations in the mammary gland.

In addition to antigen selectivity, a general hyporesponsiveness to mitogenic stimulation of milk lymphocytes relative to peripheral blood lymphocytes has been observed [136,140]. The decreased reactivity of milk lymphocytes to phytohemagglutinin may be partly the result of a relative deficiency of certain populations of T cells in milk. Macrophage–T cell interactions also have been postulated to be responsible for this relative hyporesponsiveness [140], although it is unknown whether the effects are the result of decreased helper or increased regulatory function. Studies have shown that milk lymphocytes exhibit reduced responses to allogeneic cells, but display good ability to stimulate alloreactivity [138]. Generally, the T-cell proliferative responses to phytohemagglutinin and tetanus toxoid in breast-fed infants seem to be significantly higher than the responses in bottle-fed infants, possibly secondary to the presence of maternally derived cell growth factors and other lymphokines in human milk [136,142].

Virtually all $CD4^+$ and $CD8^+$ T cells in milk bear the CD45 isoform CD45RO that is associated with immunologic memory [123,143]. In addition, the proportion of T cells that display other phenotypic markers of activation, including CD25 (IL-2R) and HLA-DR, is much greater than that in blood [123,144]. Consistent with their memory phenotype, T cells in human milk produce IFN-γ [143]. A significantly greater number of $CD4^+$ T cells in colostrum express the CD40 ligand (CD40L), which helps these cells provide help for B-cell antibody production and macrophage activation (see Chapter 4 for more details) compared with autologous or heterologous blood T cells [145]. The function of these memory T cells in the recipient human infant is currently unknown, however. Mucous membrane sites in the alimentary or respiratory tract, or both, of the recipient infant would seem to be potential entry sites for human milk leukocytes. Very few memory T cells are detected in blood in infancy [146]. It is possible that maternal memory T cells in milk may help compensate for the developmental delay in their production in the infant.

The proportion of T lymphocytes bearing the γδ T-cell receptor (γδ-TCR) is approximately two times greater in colostrum than in blood [147,148]. Human γδ-$TCR^+$ cells populate organized lymphoid tissues and represent half of the intraepithelial lymphocytes in the gut [149]. The intestinal epithelia may have a selective affinity for γδ-$TCR^+$ cells and provide a favorable environment for maternal T cells in milk to be transferred to the breast-fed infant. Evidence from experimental animal studies indicates that milk lymphocytes enter tissues of the neonate [150–153], but this has not been shown in humans.

In humans, possible transfer of maternal T-cell reactivity to tuberculin protein from the mother to the neonate through the process of breast-feeding has been suggested [106,154,155]. The implications of these observations are that maternal cellular products or soluble mediators of cellular reactivity may be transferred passively to the neonate through breast-feeding. The occurrence of such phenomena in humans has not been studied carefully, and there is no direct evidence that milk T cells, either αβ-$TCR^+$ or γδ-$TCR^+$, play a role in the transfer of adoptive immunoprotection to the recipient infant. Similarly, there is at present no evidence to suggest that there is any immunologic risk to the human neonate of maternal T cells ingested through breast-feeding.

## Neutrophils

Milk contains numerous neutrophils. Although the absolute counts in actively nursing mothers exhibit considerable variability among different samples, highest numbers are generally observed during the first 3 to 4 days of lactation. The numbers of neutrophils decrease significantly after 3 to 4 weeks of lactation, and only rare neutrophils are observed in samples collected after 60 to 80 days postpartum. Leukocytes in human milk seem to be metabolically activated. Although the neutrophils are phagocytic and produce toxic oxygen radicals, they do not respond well to chemoattractants by increasing their adherence, polarity, or directed migration in in vitro systems [156]. This diminished response was found to be due to prior activation in that the neutrophils in milk displayed a phenotypic pattern that is typical of activated neutrophils. The expression of CD11b, the α chain subunit of Mac-1, was increased, and the expression of L-selectin was decreased [122].

## Epithelial Cells

On the basis of their anatomic distribution, epithelial cells in the human mammary gland can be classified into two main types: myoepithelial and luminal. Epithelial cells of both types seem to be more heterogeneous, however, on histologic and physicochemical testing [138,157,158]. They include secretory cells, which contain abundant rough endoplasmic reticulum, lipid droplets, and Golgi apparatus. The secretory cells apparently produce casein micelle. The squamous epithelial cells usually are seen in the regions of the cutaneous junction of the nipples, especially near the galactophores. The ductal or luminal cells, which exist in clusters, have many short microvilli, tight junctions, and remnants of desmosomes [157,158].

In human milk, relatively few epithelial cells are observed in the early phases of lactation. Most epithelial cells appear after 2 to 3 weeks and are seen in appreciable numbers, even 180 to 200 days after the onset of lactation. With the possible exception of the synthesis of secretory component and casein and possibly other products, with which secretory epithelial cells have been associated in the stroma of the mammary gland, the role of epithelial cells in the milk remains to be defined.

## Possible Functions of Cellular Elements

The information reviewed so far provides strong evidence for the existence of numerous dynamic cellular reactions in the mammary gland, colostrum, and milk. The specific functional role, collectively or individually, for the epithelial cells, monocytes, neutrophils, or lymphocytes in the mammary gland or the milk remains to be defined. In view of the high degree of selectivity and the differences in the quantitative and functional distribution of cellular elements, it is suggested that the mammary gland, similar to mucosal surfaces, may function partitioned from the cellular elements in peripheral blood, in a manner similar to that for other peripheral sites (e.g., the genital tract) of the mucosal immune system. It is unknown, however, whether the characteristic proportions of macrophages, T lymphocytes, other cytotoxic cells, or epithelial cells are designed for any specific functions localized to the mammary gland in the lactating mother or to epithelium or lumen of the intestinal or respiratory mucosa of the breast-feeding infant, or both.

The observations on the transfer of delayed hypersensitivity reactions in human neonates and of graft-versus-host reactivity in the rat raise the possibility that milk cells may function as important vehicles in transfer of maternal immunity to neonates. The potential beneficial and harmful roles of such cell-mediated transfer through the mucosal routes need to be investigated further. The paucity of NK and other cytotoxic cells in the colostrum may have a role for the breast-feeding neonate, especially in influencing the antigen processing and uptake of replicating microorganisms and their immune response at systemic or mucosal levels or both. Although further elucidation of the functions of these cellular elements in the mammary glands and the suckling neonate is needed, it is likely that their presence in the milk represents a highly selective phenomenon and not a mere contamination with peripheral blood cells.

# OTHER DEFENSE FACTORS

## Direct-Acting Antimicrobial Agents

### *General Features*

The defense agents in human milk, although biochemically diverse, share the following features: (1) They usually are common to mucosal sites. (2) They are adapted to resist digestion in the gastrointestinal tract of the recipient infant. (3) They protect by noninflammatory mechanisms. (4) They act synergistically with each other or with factors produced by the infant. (5) Most components of the immune system in human milk are produced throughout lactation and during gradual weaning. (6) There is often an inverse relationship between the production of these factors in the mammary gland and their production by the infant during the same time frames of lactation and postnatal development. As lactation proceeds, the concentration of many factors in human milk declines. Concomitantly, the mucosal production of these factors increases in the developing infant. Whether the inverse relationship between these processes is due to feedback mechanisms, or the processes are independent, is unclear.

### *Carbohydrate Components*

Human milk contains several oligosaccharides and glycoconjugates, including monosialogangliosides that are receptor analogues for heat-labile toxins produced by *V. cholerae* and *E. coli* [159]; fucose-containing oligosaccharides that inhibit the hemagglutinin activity of the classic strain of *V. cholerae* [160]; fucosylated oligosaccharides that protect against heat-stable enterotoxin of *E. coli* [161]; mannose-containing, high-molecular-weight glycoproteins that block the binding of the El Tor strain of *V. cholerae* [159]; and glycoproteins and glycolipids that interfere with the binding of colonization factor (CFA/II) fimbriae on enterotoxigenic *E. coli* [162]. The inhibition of toxin binding is associated with acidic glycolipids containing sialic acid (gangliosides). Although the quantities of total gangliosides in human milk and in bovine milk are similar, the relative frequencies of each type of ganglioside in milk from these two species are distinct.

More than 50 types of monosialylated oligosaccharides have been identified in human milk, and new types are still being recognized [163]. Monosialoganglioside 3 constitutes about 74% of total gangliosides in human milk, but the percentage is much lower in bovine milk [164,165]. Also, the level of the enterotoxin receptor ganglioside $G_{M1}$ is 10 times greater in human milk than in bovine milk [165]. This difference may be clinically important because $G_{M1}$ inhibits enterotoxins of *E. coli* and *V. cholerae* [166]. Also, intact human milk fat globules and the mucin from the membranes of these structures inhibit the binding of S-fimbriated *E. coli* to human buccal epithelial cells [167].

Oligosaccharides in human milk also interfere with the attachment of *H. influenzae* and *S. pneumoniae* [168]. In this regard, *N*-acetylglucosamine (G1cNAc) (1-3) Gal-disaccharide subunits block the attachment of *S. pneumoniae* to respiratory epithelium. Human milk can interfere with the binding of human immunodeficiency virus (HIV)

envelope antigen gp120 to CD4 molecules on T cells [169]. Some evidence from animal models suggests that the oligosaccharides and glycoconjugates in human milk protect in vivo [170–172], but relevant clinical data are scarce [173] and transmission of HIV through breast-feeding is a well-established means for mother-to-infant transmission of HIV (see “Benefits and Risks of Human Milk”).

In addition to the direct antimicrobial effects of the carbohydrates in human milk, nitrogen-containing oligosaccharides, glycoproteins, and glycopeptides are growth promoters for *Lactobacillus bifidus* var. *pennsylvanicus* [174,175,176]. The ability of human milk to promote the growth of *L. bifidus* may reside in the oligosaccharide moiety [177] and peptides [178] of caseins. It seems that these factors are responsible to a great extent, however, for the predominance of *Lactobacillus* species in the bacterial flora of the large intestine of the breast-fed infant. These bacteria produce large amounts of acetic acid, which aids in suppressing the multiplication of enteropathogens. It also has been reported that *Lactobacillus* species strain GG aids in the recovery from acute rotavirus infections [179] and may enhance the formation of circulating cells that produce specific antibodies of the IgG, IgA, and IgM isotypes and serum levels of those antibodies [180].

### Generation of Antiviral, Antiparasitic Lipids from Substrata in Human Milk

Human milk supplies defense agents from fat as it is partially digested in the recipient’s alimentary tract. Fatty acids and monoglycerides produced from milk fats by bile salt–stimulated lipase or lipoprotein lipase in human milk [78], lingual/gastric lipase from the neonate from birth, or pancreatic lipase after a few weeks of age are able to disrupt enveloped viruses [181,182]. These antiviral lipids may aid in preventing coronavirus infections of the intestinal tract [183] and may defend against intestinal parasites such as *Giardia lamblia* and *Entamoeba histolytica* [184,185].

### Proteins

The principal proteins in human milk that have direct antimicrobial properties include the following.

#### α-Lactalbumin

α-Lactalbumin is a major component of the milk proteins and may possess some important functions of immunologic defense. This protein appears as large complexes of several α-lactalbumin molecules, which can induce apoptosis in transformed embryonic and lymphoid cell lines.

#### Lactoferrin

Lactoferrin, the dominant whey protein in human milk, is a single-chain glycoprotein with two globular lobes, both of which display a site that binds ferric iron [186]. More than 90% of the lactoferrin in human milk is in the form of apolactoferrin (i.e., it does not contain ferric iron) [187], which competes with siderophilic bacteria and fungi for ferric iron [188–192] and disrupts the proliferation of these microbial pathogens. The epithelial growth-promoting activities of lactoferrin in human milk also may aid in the defense of the recipient infant [193]. The mean concentration of lactoferrin in human colostrum is 5 to 6 mg/mL [194]. As the volume of milk production increases, the concentration decreases to about 1 mg/mL at 2 to 3 months of lactation [194,195].

Because of its resistance to proteolysis [196–198], the excretion of lactoferrin in stool is higher in infants fed human milk than in infants fed cow’s milk [72,199–201]. The mean intake of milk lactoferrin per day in healthy breast-fed, full-term infants is about 260 mg/kg at 1 month of lactation and 125 mg/kg by 4 months [199]. The quantity of lactoferrin excreted in the stools of low-birth-weight infants fed human milk is approximately 185 times that excreted in stools of infants fed a cow’s milk formula [202]. That estimate may be too high, however, because of the presence of immunoreactive fragments of lactoferrin in the stools of infants fed human milk [203]. Consistent with this suggestion, Prentice and colleagues [110] found that only approximately 1% of lactoferrin ingested in breast milk was excreted intact in stool by 6 weeks of postnatal age.

In addition, a significant increment in the urinary excretion of intact and fragmented lactoferrin occurs as a result of human milk feedings [110,203,204]. Stable isotope studies suggest that the increments in urinary lactoferrin and its fragments are principally from ingested human milk lactoferrin [205].

#### Lysozyme

Relatively high concentrations of lysozyme single-chain protein are present in human milk [194,195,206]. This 15-kDa agent lyses susceptible bacteria by hydrolyzing β-1,4 linkages between *N*-acetylmuramic acid and 2-acetylamino-2-deoxy-D-glucose residues in cell walls [207]. Lysozyme is relatively resistant to digestion by trypsin or denaturation owing to acid. The mean concentration of lysozyme is about 70 μg/mL in colostrum [194], about 20 μg/mL at 1 month of lactation, and 250 μg/mL by 6 months [195]. The approximate mean daily intake of milk lysozyme in healthy, full-term, completely breast-fed infants is 3 to 4 mg/kg at 1 month of lactation and 6 mg/kg by 4 months [199].

Few studies have been conducted to examine the fate of human milk lysozyme ingested by the infant. The amount of lysozyme excreted in the stools of low-birth-weight infants fed human milk is approximately eight times that of the amount excreted in the stools of infants fed a cow’s milk formula [202], but the urinary excretion of this protein does not increase as a result of human milk feedings.

#### Fibronectin

Fibronectin, a high-molecular-weight protein that facilitates the uptake of many types of particulates by mononuclear phagocytic cells, is present in human milk (mean concentration in colostrum is 13.4 mg/L) [208]. The in vivo effects and fate of this broad-spectrum opsonin in human milk are unknown.

### Complement Components

The components of the classic and alternative pathways of complement are present in human milk, but the concentrations of these components except C3 are exceptionally low [209,210].

## Anti-inflammatory Agents

Although a direct anti-inflammatory effect of human milk has not been shown in vivo, numerous clinical observations suggest that breast-feeding protects the recipient infant from injury to the intestinal or respiratory mucosa [211,212]. This protection may be partly due to the more rapid elimination or neutralization of microbial pathogens in the lumen of the gastrointestinal tract by specific or broad-spectrum defense agents from human milk, but other features of human milk suggest that this is not the sole explanation. Proinflammatory mediators are poorly represented in human milk [213]. By contrast, human milk contains a host of anti-inflammatory agents [214], including a heterogeneous group of growth factors with cytoprotective and trophic activity for the mucosal epithelium, antioxidants, antiproteases, cytokines and cytokine receptors and antagonists, and other bioactive agents that inhibit inflammatory mediators or block the selected activation of leukocytes. Similar to the antimicrobial factors, some of these factors are well adapted to operate in the hostile environment of the recipient's alimentary tract.

Growth factors in human milk include epidermal growth factor [215,216], transforming growth factor-α and transforming growth factor-β [217,218], lactoferrin [193], and polyamines [219,220]. These and a host of hormones [221], including insulin-like growth factor, vascular endothelial growth factor, growth hormone–releasing factor, hepatocyte growth factor, prolactin, leptin, and cortisol [222], may affect the growth and maturation of epithelial barriers, limit the penetration of pathogenic microorganisms and free antigens, and prevent allergic sensitization. Corticosterone, a glucocorticoid that is present in high concentrations in rat milk, speeds gut closure in the neonatal rat [223]. Although macromolecular absorption does not seem to be as marked in the human neonate [224–226], the function of the mucosal barrier system in early infancy is important to host defense, and this system may be affected by factors in human milk. In this regard, the maturation of the intestinal tract as measured by mucosal mass, DNA, and protein content of the small intestinal tract seems to be influenced by milk, particularly early milk secretions [227].

Antioxidant activity in colostrum has been shown to be associated with an ascorbate compound and uric acid [228]. In addition, two other antioxidants present in human milk, α-tocopherol [229,230] and β-carotene [230], are absorbed into the circulation by the recipient gastrointestinal mucosa. Serum vitamin E concentrations increase in breast-fed infants from a mean of 0.3 mg/mL at birth to approximately 0.9 mg/mL on day 4 of life [229].

Very high concentrations of the pleiotropic anti-inflammatory and immunoregulatory cytokine IL-10, which attenuates dendritic cell, macrophage, T-cell, and NK-cell function, have been shown in samples of human milk collected during the first 80 hours of lactation [231]. IL-10 is present not only in the aqueous phase of the milk, but also in the lipid layer. Its bioactive properties were confirmed by the finding that human milk samples inhibited blood lymphocyte proliferation and that this property was greatly reduced by treatment with anti–IL-10 antibody. Mice with a targeted disruption in the IL-10 gene, when raised under conventional housing conditions, spontaneously develop a generalized enterocolitis that becomes apparent at the age of 4 to 8 weeks (time of weaning) [232]. These observations suggest that IL-10 in rat milk, and perhaps in human milk, may play a crucial role in the homeostasis of the immature intestinal barrier by regulating aberrant immune responses to foreign antigens.

Soluble cytokine receptors and cytokine receptor antagonists also are potent anti-inflammatory agents. Human colostrum and mature milk have been shown to contain biologically active levels of IL-1 receptor antagonist (IL-1Ra) and soluble TNF-α receptors I and II (sTNF-αRI and sTNF-αRII) [233]. The in vivo relevance of these observations also has been shown in a chemically induced colitis model of rats. Animals with colitis fed human milk had significantly lower neutrophilic inflammation than animals fed either chow or infant formula [234]. Similar "protective" effects were seen in rats with colitis fed an infant formula supplemented with IL-1Ra [234], suggesting that this anti-inflammatory agent present in milk may contribute to the broad protection against different injuries provided by human milk feeding.

The presence in human milk of platelet-activating factor acetylhydrolase (PAF-AH), the enzyme that catalyzes the degradation and inactivation of PAF, is intriguing [235]. Elevated serum concentrations of PAF have been found in rat and human neonates with necrotizing enterocolitis, whereas the concentrations of PAF-AH were found to be significantly lower than in control (unaffected) neonates [236,237]. Serum concentrations of PAF-AH at birth are less than concentrations in adults and gradually increase [237]. The enzyme is actively transferred from the mucosal to the serosal fluid in intestine of neonatal rats, particularly in the earliest postnatal period [238]. Other anti-inflammatory factors present in human milk include an IgE-binding factor, related antigenically to FcεRII (the lower affinity receptor for IgE), that suppresses the in vitro synthesis of human IgE [239] and the glycophosphoinositol-containing molecule protectin (CD59) that inhibits insertion of the complement membrane attack complex to cell targets [240]. The in vivo fate and effects of these anti-inflammatory factors in human milk are still poorly understood.

## Modulators of the Immune System

Several seemingly unrelated types of observations suggest that breast-feeding modulates the development of the immune system of the recipient infant.

- Prospective and retrospective epidemiologic studies have shown that breast-fed infants are at less risk for development of certain chronic immunologically mediated disorders later in childhood, including allergic diseases [241], Crohn disease [242], ulcerative colitis [243], insulin-dependent diabetes mellitus [244], and some lymphomas [245].
- Humoral and cellular immune responses to specific antigens (i.e., vaccines) given during the first year of life seem to develop differently in breast-fed and in formula-fed infants. Several studies have reported increased serum antibody titers to *H. influenzae* type b

polysaccharide [246], oral poliovirus [247], tetanus [248], and diphtheria toxoid [249] immunizations in breast-fed infants. In regard to cell-mediated immunity, breast-fed infants given bacille Calmette-Guérin vaccine at birth or later show a significantly higher lymphocyte transformation response to purified protein derivative than infants who were never breast-fed [249]. Maternal renal allografts survive better in individuals who were breast-fed than in individuals who were not [250–252]. In this respect, the in vitro allogeneic responses between the blood lymphocytes of mothers (stimulating cells) and their infants (responding cells), as measured by an analysis of the frequencies of cytotoxic T lymphocyte (CTL) precursors directed against HLA alloantigens (CTL allorepertoire), are low in breast-fed infants [253].

- Increased levels of certain immune factors in breast-fed infants, which could not be explained simply by passive transfer of those substances, also suggest immunomodulatory activity of human milk. Breast-fed infants produce higher blood levels of IFN in response to respiratory syncytial virus infection [254]. It also was found that the increments in blood levels of fibronectin that were achieved by breast-feeding could not be due to the amounts of that protein in human milk [208]. In addition, it was found that human milk feeding led to a more rapid development in the appearance of sIgA in external secretions [202,204,110,248,255], some of which, such as urine, are far removed anatomically from the route of ingestion [204,110].
- Breast milk inhibits the response of human adult and fetal intestinal epithelial cells, dendritic cells, and monocytes to ligand-induced activation by toll-like receptor 2 and TLR3, but augments activation via TLR4 and TLR5 [256]. Inhibition of activation via TLR2 seemed to be mediated by a soluble form of this receptor [257], whereas augmentation of TLR4 signaling was associated with an as yet uncharacterized protein. These immunomodulatory activities were not present in infant formula. These results suggest that breast milk can modulate the gut innate immune recognition of and response to microbes, which may affect the nature of the gut microbial flora (e.g., microbiome) and risk for disease in early and later life [258,259].

These and other observations suggest that the ability of human milk to modulate the development of the infant's own mucosal and systemic immune systems may be associated with immunoregulatory factors present in colostrum and in more mature milk. Several different types of immunomodulatory agents can be identified in human milk [214]. Among the numerous substances with proven or potential ability to modulate the infant immune response are prolactin [260], α-tocopherol [229], lactoferrin [261], nucleotides [67], anti-idiotypic sIgA [262], and cytokines [263]. It is evident that many of these factors in milk have other primary biologic functions, as in the case of hormones or growth factors, and that their potential as immunoregulatory agents overlaps with their antimicrobial or anti-inflammatory properties [214].

### *Cytokines in Human Milk*

In the 1990s, several cytokines, chemokines, and growth factors that mediate the effector phases of natural and specific immunity were discovered in human milk, and many more have been identified subsequently (Table 5–8). Human milk displays numerous biologic activities characteristic of cytokines, including the stimulation of growth, differentiation of immunoglobulin production by B cells [125,264,265], enhancement of thymocyte proliferation [266], inhibition of IL-2 production by T cells [267], and suppression of IgE production [239]. IL-1β [268] and TNF-α [269] were the first two cytokines quantified in human milk. In colostrum, TNF-α is present mainly in fractions of molecular weight of 80 to 195 kDa, probably bound to its soluble receptors [233]. Milk TNF-α is secreted by milk macrophages [269,270] and by the mammary epithelium [271].

IL-6 was first shown in human milk by a specific bioassay [272]. In this study, anti–IL-6–neutralizing antibodies inhibited IgA production by colostrum mononuclear cells, suggesting that IL-6 may be involved in the production of IgA in the mammary gland. The presence of IL-6 in milk also has been shown by immunoassays [269,271,273,274]. Similarly, IL-6 is localized in high-molecular-weight fractions of human milk [273]. The association of IL-6 with its own receptor has not been studied in milk, although the expression of IL-6 receptor by the mammary epithelium [271] and in secreted form in the milk [233] may explain the high molecular weight of this cytokine in human milk. The expression of IL-6 messenger ribonucleic acid (mRNA) and protein in milk cells and in the mammary gland epithelium suggests that milk mononuclear cells and the mammary gland are likely major sources of this cytokine [270,271,275].

The presence of IFN-γ in human milk also has been reported [148,271,274], although some investigators have found significant levels of IFN-γ only in milk samples obtained from mothers whose infants had been delivered

**TABLE 5–8** Cytokines, Chemokines, and Colony-Stimulating Factors in Human Milk

| Cytokines | Chemokines | Colony-Stimulating Factors |
|---|---|---|
| IL-1β | CXCL1 | G-CSF |
| IL-2 | CXCL8 (IL-8) | GM-CSF |
| IL-4 | CXCL9 | M-CSF |
| IL-6 | CXCL10 | Erythropoietin |
| IL-7 | CCL2 | |
| IL-8 | CCL5 | Interferons |
| IL-10 | CCL11 | |
| IL-13 | | |
| IL-15 | TGF-β | |
| IFN-γ | | |
| TNF-α | | |

*G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; M-CSF, monocyte colony-stimulating factor; TGF-β, transforming growth factor-β; TNF-α, tumor necrosis factor-α.*
*Adapted from references 277 and 278 and other sources.*

by cesarean section. The significance of this observation is unclear at present. IFN-$\gamma$ bioactivity and its association with specific subsets of milk T cells also remains to be determined [148]. (The presence and possible function of IL-10 in human milk are discussed in "Anti-inflammatory Agents.")

Chemokines are a novel class of small cytokines with discrete target cell selectivity that are able to recruit and activate different populations of leukocytes (see Chapter 4). Chemokines are grouped into families, which are defined by the spacing between cysteine residues (see Chapter 4). CXC chemokines, in which cysteine pairs are separated by one amino acid, and CC chemokines, in which paired cysteines are adjacent to each other, are found in human milk. Certain CXC chemokines that contain an ELR motif, including CXCL8 (also known as IL-8) and CXCL1 (GRO-$\alpha$), predominantly attract neutrophils, whereas basophils, eosinophils, dendritic cells, monocytes, and specific subsets of T and B lymphocytes are attracted by specific CC chemokines and non-ELR CXC chemokines. The presence of many CXC and CC chemokines has been described in human milk (see Table 5–8) [275–278].

Colony-stimulating factors—highly specific protein factors that regulate cell proliferation and differentiation in the process of hematopoiesis—are also present in human milk [148,279–282]. The concentrations of monocyte colony-stimulating factor in particular seem to be 10-fold to 100-fold higher in human milk than in serum, and monocyte colony-stimulating factor evidently is produced by epithelial cells of the ducts and alveoli of the mammary gland under the regulatory activity of female sex hormones [281].

Although it is tempting to speculate that cytokines present in milk may be able to interact with mucosal tissues in the respiratory and alimentary tracts of the recipient infant, the functional expression of specific receptors for cytokines on epithelial or lymphoid cells in the airway and gastrointestinal mucosa has not been fully explored [214]. A receptor-independent mechanism of cytokine uptake by the gastrointestinal mucosa during the neonatal period has not been shown to date.

Whether and to what extent cytokines in breast milk contribute to the beneficial effects of human milk in the gut and elsewhere is largely unknown. Indirect evidence suggests that IL-7, which is a growth factor for T-cell progenitors (and for memory T cells), in breast milk may support thymic growth. Thymus size was found to be larger in breast-fed than in formula-fed 4-month-old infants in Denmark [283], and thymus size and IL-7 content of breast milk were directly correlated with each other in exclusively breast-fed infants in the Gambia [284]. In the latter study, reduced breast milk content of IL-7 was observed in the "hungry season" in association with reduced thymus size and thymic production of T cells; however, whether IL-7 in breast milk was absorbed intact and causally related to greater thymus size or was merely a surrogate for other factors cannot be determined from this study.

## MILK AND ALTERED PREGNANCY

Several investigators have examined the effects of prematurity, early weaning, galactorrhea, and maternal malnutrition on the process of lactation. The immunologic aspects of these studies have focused largely on evaluation of the total content of sIgA and specific antibody activity. As described previously, the mammary secretions of the nonlactating breast contain sIgA, although the amount seems to be much lower than in the lactating breast [285]. Mammary secretions of patients with galactorrhea seem to contain sIgA in concentrations similar to those of normal postpartum colostrum [286]. Although malnutrition has been associated with reduced secretory antibody response in other external secretions, maternal malnutrition does not seem to affect the total sIgA concentration or antimicrobial-specific antibody activity in the milk [287]. By contrast, as noted in the preceding paragraph, poor maternal nutrition in the "hungry season" in the Gambia was associated with decreased thymus size [284].

The nutritional and immunologic composition of milk from mothers of premature infants seems to be significantly different from that of milk from mothers of infants born at term [16,49,195,288]. Comparative studies conducted during the first 12 weeks of lactation suggest that the mean concentrations of lactoferrin and lysozyme are higher in preterm than in term milk. sIgA is the predominant immunoglobulin in preterm and in term milk, although the sIgA concentration seems to be significantly higher in preterm milk collected during the first 8 to 12 weeks of lactation. sIgA antibody activity against certain organisms (*E. coli* somatic antigen) in the preterm milk was observed to be less than, or at best similar to, that found in term milk. In addition, the number of lymphocytes and macrophages in milk seems to be lower at 2 weeks, but significantly higher at 12 weeks in milk from mothers with preterm (born at 34 to 38 weeks of gestational age) infants than in milk from mothers with full-term infants [288]. The authors of these investigations have proposed that some of the observed changes may reflect the lower volume of milk produced by mothers delivered of preterm infants. The possibility remains that changes in the immunologic profile of preterm milk may be a consequence of inadequate stimulation by the preterm infant, alterations in the maternal hormonal milieu, or other factors underlying premature delivery itself.

# BENEFITS AND RISKS OF HUMAN MILK

## BENEFITS

### Gastrointestinal Homeostasis and Prevention of Diarrhea

Development of mucosal integrity in the gut seems to depend on maturation of the mucosal tissue itself and the establishment of a normal gut flora. The former represents an anatomic and enzymatic blockage to invasion of microorganisms and antigens, and the latter represents an inhibition of colonization by pathogenic bacteria. Although permeability of the neonatal gut to immunoglobulin is short-lived, damaged neonatal gut is permeable to a host of other proteins and macromolecules for several weeks or longer. Large milk protein peptides and bovine serum albumin have been shown to enter the

circulation and to induce a circulating antibody response. The inflamed or ischemic gut is even more porous to antigens and pathogens. Various proven and presumed mechanisms for the role of sIgA and the normal flora have been proposed to compensate for these temporary inadequacies.

Breast-feeding has been strongly implicated in supporting gastrointestinal homeostasis in the neonate and in establishing normal gut flora. Observations have shown a reduced rate of diarrheal disease in breast-fed infants, even in the face of contamination of the fed milk with *E. coli* and *Shigella* species [289]. A preventive and therapeutic role for breast-feeding also has been suggested in nursery outbreaks of diarrheal disease caused by enteropathogenic strains of *E. coli* [290] and rotavirus [291]. Breast-feeding plays an inhibitory role in the appearance of *E. coli* O83 agglutinins found in the feces of colonized infants. In addition, the diverse serotypes of aerobic, gram-negative bacilli present in the oropharynx and the gastrointestinal tract of the neonate may serve as a source of antigen to boost the presensitized mammary glands, leading to a further modulation of specific bacterial growth in the mucosa [292]. The precise role of antibody that blocks adherence of these pathogens to the gut and the effects of other factors, such as lactoperoxidase, lactoferrin, lysozyme, and the commensal flora, in those situations are uncertain.

Extensive epidemiologic evidence supports the "prophylactic value" of breast-feeding, particularly exclusive breast-feeding. in the first 6 months of life with the addition of complementary feeding thereafter, in the prevention or amelioration of diarrheal disease in infants and young children in developed and developing nations and is summarized in several reviews [1,3,86,87,293]. Ample experimental animal data on the value of specific colostral antibody in preventing diarrheal illness are available from studies of colostral deprivation. These include colibacteriosis associated with *E. coli* K88 in swine; rotaviral gastroenteritis in cattle, swine, and sheep; and diarrheal illness associated with transmissible gastroenteritis of swine [294]. In humans, cholera is rare in infancy, especially in endemic areas where the prevalence of breast-feeding is high. The experience with an outbreak of cholera in the Persian Gulf lends support to the possibility that the absence of breast-feeding is an important variable in increasing the risk of cholera in infancy.

A few reports have claimed that nursery outbreaks of diarrhea associated with enteropathogenic strains of *E. coli* can be interrupted by use of breast milk. Conflicting data exist regarding prevention of human rotaviral infection and disease. Evaluation of nursery outbreaks of rotaviral disease has suggested that the incidence of infection and of illness was lower in breast-fed infants, but the incidence of symptoms in formula-fed infants also was very low. Studies done in Japan have noted a fivefold decrease in incidence of rotaviral infection among breast-fed infants younger than 6 months. Most rotavirus infections in neonates are asymptomatic, regardless of breast-feeding or bottle-feeding [295–297]. On the basis of careful clinical observations, Bishop and coworkers[298] in Australia first questioned the positive effects of breast-feeding in rotavirus infection.

More recent case-control studies of enteric viral infections in breast-fed infants have suggested that breast-feeding may protect infants from hospitalization rather than from infection itself [299,300]. Longitudinal follow-up of a large cohort of infants during a community outbreak of rotavirus has shown that attack rates of rotavirus infection were similar in breast-fed and in bottle-fed infants. The frequency of clinical disease with diarrhea seemed to be significantly lower in breast-fed infants, however. The protection observed in these patients was more a reflection of altered microbial flora from breast-feeding than of specific immunologic protection against rotavirus. Breast milk contains sIgA directed against rotavirus, with the greatest concentrations in colostrum and lower amounts in mature milk; neutralization of rotavirus by breast milk correlates imperfectly with antibody concentrations measured by enzyme immunoassay, suggesting that other factors present in milk contribute to rotavirus neutralization [301]. It seems that breast-feeding provides significant protection against diarrheal disease, although the mechanisms of such protection remain to be more fully defined [299,300].

## Necrotizing Enterocolitis

Necrotizing enterocolitis is a complex illness of the stressed premature infant, often associated with hypoxia, gut mucosal ischemia, and necrolysis and death [302,303]. Clinical manifestations have occasionally been associated with bacteremia and invasion by gram-negative bacilli, particularly *Klebsiella pneumoniae*, into the intestinal submucosa. Clinical manifestations include abdominal distention, gastric retention, and bloody diarrhea. Classic radiographic findings include air in the bowel wall (pneumatosis intestinalis), air in the portal system, and free infradiaphragmatic air (signifying perforation). Treatment involves decompression, systemic antibiotics, and, often, surgery [304–306].

Numerous studies have suggested a beneficial role of breast milk in preventing or modifying the development of necrotizing enterocolitis in high-risk human infants. Some pediatric centers have claimed virtual absence of necrotizing enterocolitis in breast-fed infants; however, many instances of the failure of milk feeding to prevent human necrotizing enterocolitis also have been reported [307]. Outbreaks of necrotizing enterocolitis related to *Klebsiella* and *Salmonella* species secondary to banked human milk feedings have been documented [124,308,309]. In an asphyxiated neonatal rat model of necrotizing enterocolitis, the entire syndrome could be prevented with feeding of maternal milk. The crucial factor in the milk seemed to be the cells, probably the macrophages [124]. It also is possible that antibody and nonspecific factors play a role, as does establishment of a gut flora. Prophylactic oral administration of immunoglobulin has been found to have a profound influence on the outcome of necrotizing enterocolitis in well-controlled studies [309]. Penetration of the gut by pathogens and antigens is increased with ischemic damage, and noncellular elements of milk may aid in blockage of this transit [310].

Necrotizing enterocolitis is a complex disease entity whose pathogenesis and cause remain to be defined.

Although breast-feeding may be protective, many other factors are related to the mechanism of mucosal injury and the pathogenesis of this syndrome.

## Neonatal Sepsis

The incidence of bacteremia among premature infants fed breast milk has been suggested to be significantly lower than that among premature infants receiving formula feedings or no feeding [311–313]. A decrease in the incidence of neonatal sepsis, including sepsis associated with gram-negative bacilli and *E. coli* serotype K1, also has been linked to breast-feeding [314–316]; antibody and compartmentalized cellular reactivity to this serotype have been shown in human colostrum. Other studies have failed, however, to show clear evidence of protection against systemic infection in breast-fed infants [317–319]. A review of the evidence for protection of very low birth weight neonates from late-onset sepsis through the use of human milk suggested that the quality of the current evidence was insufficient to show a beneficial effect [320], although other authors have reached different conclusions [84,321].

## Prevention of Atopy and Asthma

One of the most challenging developments in human milk research has been the demonstration in breast-fed infants of a reduced incidence of diseases with autoregulated or dysregulated immunity, long after the termination of breast-feeding [241–245]. Since the first report in 1936 [322], numerous published studies have addressed the effect of infant feeding on the development of atopic disease and asthma. Beneficial results of breast-feeding as prophylaxis against atopy have been observed in most of the studies; however, in others, beneficial effects were reported only in infants with a genetically determined risk for atopic disease. Finally, no beneficial effect at all or even an increased risk has been suggested in some breast-fed infants.

Kramer [323], in an extensive meta-analysis of 50 studies published before 1986 that focused on infant feeding and atopic disease, attempted to shed some light on the controversy. Of the 13 studies on asthma included in this analysis, 7 claimed a protective effect of breast-feeding, whereas 6 claimed no protection. Several serious methodologic drawbacks have been noted in this analysis, however. In many of the studies analyzed, early infant feeding history was obtained months or years after the feeding period, ascertainment of the infant feeding history was obtained by interviewers who were aware of the disease outcome, or insufficient duration and exclusivity of breast-feeding were documented; all were confounding variables that considered inappropriate "exposure standards." Nonblind ascertainment of disease outcome was found to be the most common violation of the "outcome standards."

Kramer's analysis also found that failure to control for confounding variables was a common violation in "statistical analysis standards" identified in several studies. The effect of infant feeding on subsequent asthma may be confounded by other variables that are associated with infant feeding and with unique investigational conditions. Factors that seem to have the greatest potential for confounding effects include family history of atopic disease, socioeconomic status, and parental cigarette smoking. Only 1 of 13 studies on asthma included in the meta-analysis adequately controlled for these confounding factors. Three of the studies that did not show a protective effect of breast-feeding on asthma had inadequate statistical power. The effect of infant feeding on the severity of outcome and on the age at onset of the disease was virtually ignored in most of the studies [323].

Although this extensive meta-analysis may suggest some uncertainty about the prophylactic benefit of breast-feeding, other studies strongly support a positive effect of breast-feeding on the development of atopic disease and asthma. The first study [241] consisted of prospective, long-term evaluation from infancy until age 17 years; the prevalence of atopy was significantly higher in infants with short-duration (<1 month) or no breast-feeding, which increased to a demonstrable difference by age 17 years, than in infants with intermediate-duration (1 to 6 months) or prolonged (>6 months) breast-feeding. The differences in the prevalence of atopy persisted when the groups were divided according to positive or negative atopic heredity. The atopy manifestations in the different infant feeding groups did not remain constant with age. In particular, respiratory allergy, including asthma, increased greatly in prevalence up to age 17 years, with a prevalence of 64% in the group with short-duration or no breast-feeding [241].

In the second study, a prospective, longitudinal study of the prevalence and risk factors for acute and chronic respiratory illness in childhood, the investigators examined the relationship of infant feeding to recurrent wheezing at age 6 years and the association with lower respiratory tract illnesses with wheezing early in life [324]. Children who were never breast-fed had significantly higher rates of recurrent wheezing at 6 years of age. Increasing duration of breast-feeding beyond 1 month was not associated with significantly lower rates of recurrent wheezing. The effect of breast-feeding was apparent for children with and without wheezing lower respiratory tract illnesses in the first 6 months of life. In contrast with the findings of the first study, however, the effect of breast-feeding was significant only among nonatopic children [324].

The exact mechanisms by which breast-feeding seems to confer long-lasting protection against allergic sensitization are poorly understood. It is likely, however, that multiple synergistic mechanisms may be responsible for this effect, including (1) maturation of the recipient gastrointestinal and airway mucosa, promoted by growth factors present in human milk [216–218]; (2) inhibition of antigen absorption by milk sIgA [325]; (3) reduced incidence of mucosal infections and consequent sensitization to bystander antigens [326]; (4) changes in the microbial flora of the intestine of breast-fed infants [302]; and (5) direct immunomodulatory activity of human milk components on the recipient infant [214].

Numerous earlier and more recent studies have greatly contributed to the understanding of macromolecular transport across the immature gut and its consequences in terms of the generation of circulating antibody or immune complexes, the processes that are blocked

predominantly by sIgA, the glycocalyx, and the intestinal enzymes. These mucosal immunologic events have been the basis for the concept of immune exclusion. Immune exclusion is not absolute, however, because uptake of some antigens across the gut may be enhanced rather than blocked by interaction with antibody at the mucosal surface. Beginning with the observations of IgA-deficient patients, it has become clear that the absence of the IgA barrier in the gut is associated with an increased incidence of circulating antibodies directed against many food antigens and an increased occurrence of atopic-allergic diseases [325]. Some studies have noted complement activation in serum after feeding of bovine milk to children with cow's milk allergy. The neonate is similar in some respects to the IgA-deficient patient [327], and increased transintestinal uptake of food antigen with consequent circulating antibody formation in the premature infant has been reported [328]. Other studies have suggested that early breast-feeding, even of short duration, is associated with a decreased serum antibody response to cow's milk proteins [226]. Prolonged breast-feeding not only may partially exclude foreign antigens through immune exclusion, but may also, because the mother's milk is the infant's sole food, prevent their ingestion [329]. Intact bovine milk proteins and other food antigens and antibodies have been observed, however, in samples of colostrum and milk [8].

### Other Benefits

Epidemiologic evidence suggests that bacterial and viral respiratory infections are less frequent and less severe among breast-fed infants in various cultures and socioeconomic settings [330,331]. Antibodies and immunologic reactivity directed against herpes simplex virus, respiratory syncytial virus, and other infectious agents [92,102,164,331,332] and that protect against enterovirus infections [333] have been quantitated in colostrum and milk. Adoptive experiments in suckling ferrets have shown that protection of the young against respiratory syncytial virus can be transferred in colostrum containing specific antibody. The neonatal ferret gut is quite permeable, however, to macromolecules and permits passage of large quantities of virus-specific IgG. In the absence of either documented antibody or cellular transfer in the human neonate across the mucosa, any mechanisms of protection against respiratory syncytial virus and other respiratory pathogens remain obscure.

Data are lacking in humans regarding passive protection on other mucosal surfaces, such as the eye, ear, or genitourinary tract. Some epidemiologic evidence suggests that recurrence of otitis media with effusion is strongly associated with early bottle-feeding and that breast-feeding may confer protection against otitis media with effusion for the first 3 years of life [334]. Foster feeding–acquired antibody to herpes simplex virus has been found to result in significant protection against reinfection challenge in experimental animal studies [332].

Numerous other benefits have been associated with breast-feeding, including natural contraception during active nursing [335] and protection against sudden infant death syndrome [336], diabetes [337], obesity [338], and high cholesterol level and ischemic heart disease later in life [42]. Of particular more recent interest has been the association of breast-feeding with improved intellectual performance in older children. Several studies have shown enhanced cognitive outcome in breast-fed children, although controversy exists regarding the mechanisms by which such improved performance may occur [339–341]. Health benefits for the mother also may be associated with breast-feeding: A reduced incidence of breast cancer has been noted in women who have lactated [342].

## POTENTIAL RISKS

### Noninfectious Risks

Human milk is the optimal form of nutrition for healthy term infants in almost all situations. The failure to initiate lactation properly during early breast-feeding may present a risk of dehydration to the infant because insufficient fluids may be ingested. Inappropriate introduction of bottles and pacifiers also may interfere with proper induction of lactation. Later in lactation, introduction of bottles may induce premature weaning as the result of a reduction in the milk supply.

Some circumstances have been identified in which breast-feeding is contraindicated and others have been identified in which continued breast-feeding should be conducted with caution to protect the infant [3]. Infants with inherited metabolic diseases may require alternative forms of nutrition: neonates with classic galactosemia owing to deficiency of galactose-1-phosphate uridyltransferase should receive lactose-free milk (lactose is a glucose-galactose disaccharide); infants with phenylketonuria may receive some human milk to support their requirement for phenylalanine, but often may be better managed by use of specially prepared commercial milks. Mothers who have received radionuclides for diagnostic or therapeutic purposes should use alternative forms of nutrition for the days to weeks required for these compounds to be eliminated, as should mothers receiving certain chemotherapeutic and immunosuppressive agents and actively using drugs of abuse, including amphetamines, cocaine, heroin, and phencyclidine [343]. Low-level maternal exposure to environmental chemicals and tobacco smoking should be avoided as much as possible, but are not a contraindication to breast-feeding.

Antimicrobial agents taken by mothers only rarely represent a contraindication to breast-feeding. As first principles, antimicrobials that may be safely given to infants may be safely given to their lactating mothers, and blood concentrations that may be achieved through breast milk ingestion are lower than therapeutic doses used in infants [344]. Breast-feeding by mothers receiving chloramphenicol is contraindicated because its use may be associated with fatal complications in newborn infants. The effects of metronidazole are uncertain, but to minimize exposure to this drug, which is mutagenic in bacteria, mothers receiving single-dose therapy should discontinue breast-feeding for 12 to 24 hours [343]. Excretion of antibiotics in human milk is also discussed in Chapter 37. For up-to-date information regarding drugs and lactation, the reader should consult http://www.toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT.

Several instances of specific nutrient deficiencies in breast-fed infants have been described, specifically related to lack of vitamin K, vitamin D, vitamin $B_{12}$, folic acid, vitamin C, and carnitine. In each of these instances, several case reports have appeared warning against deficiencies that have resulted in clinical consequences to the neonate. Hemorrhagic disease reported in a few breast-fed infants was successfully treated with vitamin K [345]. These infants did not receive vitamin K at birth. Mothers who practice unusual dietary habits, such as strict vegetarianism, may have reduced levels of vitamin $B_{12}$ and folic acid in their milk, and deficiencies in breast-fed infants of such mothers have been reported [346,347]. Cases of rickets in breast-fed infants have been reported, particularly during winter among infants not exposed to the sun [34,348]. Deficiency of carnitine, a nutrient responsible for modulating fat absorption, also has been reported to result in clinical symptoms in breast-fed infants in mothers ingesting unusual diets [61,349]. These concerns can best be addressed in almost all cases by counseling mothers regarding nutritional practices and by the provision of supplemental vitamins and other micronutrients when appropriate; this is the case in the developed world and even more so in the developing world where the untoward consequences of not breast-feeding are particularly great [293].

Management of hyperbilirubinemia associated with breast-feeding has been an area of some controversy. Present recommendations are for continued breast-feeding with efforts to increase the volume of milk ingested, with the provision that with severe hyperbilirubinemia a brief interruption of breast-feeding might be appropriate [3].

## Infectious Risks

Human milk may contain infectious agents that are secreted into the milk; enter milk during lactation; or are acquired when milk is improperly collected, stored, and later fed to the infant. Formal training and evaluation of breast-feeding practices by trained caregivers is the best way to reduce these risks; routine culture or heat treatment of a mother's milk even when it is stored and later used to feed her infant is not cost-effective [3].

Stored milk is now commonly used to feed infants when their mothers are unable to breast-feed directly because of work or travel constraints or when the infant is premature or otherwise unable to breast-feed effectively. Inadvertent feeding of stored milk from other than the birth mother has occurred in nurseries. If this occurs, the AAP recommends that this be handled in the same manner as if accidental exposure to blood or other body fluids has occurred [344] (see Chapter 35 for additional information).

In the United States, the Human Milk Banking Association of North America (http://www.hmbana.org/) collects human donor milk for the purpose of administration to infants whose mothers' milk is unavailable or inadequate. Members of this association follow guidelines formulated in consultation with the U.S. Food and Drug Administration (FDA) and Centers for Disease Control and Prevention. These guidelines help to ensure that donors are screened for transmissible infections and that the milk is carefully collected, processed, and stored. Using these practices, donor milk is collected and pooled and subjected to Holder pasteurization (62.5° C) for 30 minutes, which reliably kills bacteria and inactivates HIV and cytomegalovirus (CMV) and eliminates or substantially reduces the amounts of other viruses. The pooled milk is tested to ensure that it meets standards and is frozen for later distribution and use.

### Bacterial Infections

Transmission of bacterial pathogens, including *S. aureus*, group B streptococci, mycobacteria, and other species, may occur through breast-feeding (Table 5–9). Mastitis and breast abscesses may be associated with substantial concentrations of bacteria in the mother's milk. Generally, feeding an infant from a breast affected by an abscess is not recommended [344]. Infant feeding on the affected breast may be resumed, however, 24 to 48 hours after drainage and the initiation of appropriate antibiotic therapy. Mastitis usually resolves with appropriate antimicrobial therapy and with continued lactation, even if feeding from the affected breast is temporarily interrupted.

**TABLE 5–9** Infectious Agents Transmitted through Breast-Feeding

| Organism | Transmission | Disease | Intervention |
|---|---|---|---|
| Cytomegalovirus | + | VLBW infants | Consider risk/benefit |
| Hepatitis B virus | + | + | HBIG/hepatitis B vaccine |
| Hepatitis C virus | HIV+ mothers only | ? | See text |
| Herpes simplex virus | + | + | See text |
| HIV | + | + | U.S.: Do not breastfeed* |
| HTLV-1 | + | ± | U.S.: Do not breastfeed* |
| HTLV-2 | + | ± | U.S.: Do not breastfeed* |
| Rubella virus | + | 0 | None |
| West Nile virus | ± | ± | None |
| Group B streptococci | + | ± | See text |
| *Staphylococcus aureus* | + | ± | See text |
| *Mycobacterium tuberculosis* | + | – | See text |

**In many other parts of the world, the benefits of breast-feeding often outweigh the risks of alternative methods of infant feeding. See text for discussion of risk versus benefit in other parts of the world.*
*HBIG, hepatitis B immunoglobulin; HIV, human immunodeficiency virus; HTLV, human T-lymphotropic virus; VLBW, very low birth weight.*

In both of these conditions, feeding from the unaffected breast need not be interrupted.

Mothers with active tuberculosis should refrain from breast-feeding for at least 2 weeks or longer after institution of appropriate treatment if they are considered contagious. This recommendation also applies to the uncommon situation where mastitis or breast abscess is caused by *Mycobacterium tuberculosis* [344].

## Viral Infections

Viruses that have been detected in human milk include CMV, hepatitis B (HBV) and hepatitis C (HCV) viruses, herpes simplex virus, HIV-1, human T-lymphotropic virus 1 (HTLV-1) and HTLV-2, rubella virus, and West Nile virus (see Table 5–9) [344]. It is unknown whether varicella virus is secreted into human milk. Although some of these viruses do present a risk to the infant, for most, but not all, the benefits of breast-feeding to the infant are greater than the risk.

### Cytomegalovirus Infection

CMV infection is a common perinatal infection. The virus is shed in the milk in about 25% of infected mothers. Although breast-feeding from infected mothers may result in seroconversion in 70% of breast-feeding neonates, the infection often is not associated with clinical symptoms of disease. Infants with very low birth weight (<1500 g) may exhibit evidence of clinical disease, however, with thrombocytopenia, neutropenia, or hepatosplenomegaly seen in 50% of very low birth weight infants infected through breast-feeding. The decision to breast-feed a premature infant by an infected mother should be based on weighing the potential benefits of human milk versus the risk of CMV transmission [344].

### Hepatitis B Virus Infection

Hepatitis B surface antigen has been detected in milk of HBV-infected mothers. Nevertheless, breast-feeding does not increase the risk of HBV infection among these infants. Infants born to HBV-positive mothers should receive hepatitis B immunoglobulin and the recommended series of hepatitis B vaccine without any delay in the institution of breast-feeding [344].

### Hepatitis C Virus Infection

The RNA of HCV and antibody to HCV have been detected in the milk from infected mothers. Transmission via breast-feeding has not been documented in anti-HCV–positive, anti-HIV–negative mothers, but is a theoretical possibility about which these mothers should be informed before deciding whether they will breast-feed. According to current guidelines, HCV infection does not contraindicate breast-feeding [344].

### Herpes Simplex Virus Type 1

Herpes simplex virus transmission directly from maternal breast lesions to infants has been shown. Women with lesions on one breast may feed from the other unaffected breast, making sure that lesions on the other breast or on other parts of the body are covered and using careful hand hygiene [344].

### Human Immunodeficiency Virus Type 1

Numerous studies have shown HIV in milk [350–354]. The findings include isolation of HIV from milk supernatants collected from symptom-free women and from cellular fractions of maternal milk, recovery of HIV virions in the histiocytes and cell-free extracts of milk by electron microscopy, and detection of viral DNA by polymerase chain reaction in greater than 70% of samples from HIV-seropositive lactating women.

Transmission of HIV through breast-feeding may account for one third to one half of all HIV infections globally, with risk of transmission being approximately 15% when breast-feeding continues beyond the first year of life [355,356]. The risk of postnatal HIV transmission seems to be constant throughout the first 18 months of life; risk is cumulative as duration of breast-feeding increases [357]. Risk of transmission via breast milk is greater when maternal HIV infection is acquired during lactation; when viral load is greater or maternal disease is more advanced; when infants are breast-fed and formula-fed; when the mother has bleeding or cracked nipples, mastitis, or a breast abscess; and when the infant has thrush or certain other coinfections (see Chapter 21 for more details).

Current recommendations from the AAP [344] and other authorities [358] state that in populations such as that of the United States, in which the risk of death from infectious diseases and malnutrition is low and in which safe and effective alternative sources of feeding are readily available, HIV-infected women should be counseled not to breast-feed their infants and not to donate milk. One report found that highly active antiretroviral therapy administered during pregnancy or postpartum suppresses HIV RNA, but not DNA in breast milk [359]. At present, the AAP recommends that infants of HIV-infected mothers in the United States receiving highly active antiretroviral therapy should not be breast-fed.

Despite the potential risk of HIV infection in infants of HIV-infected breast-feeding mothers, consideration of cessation of breast-feeding must be balanced against the other beneficial effects described in this chapter. In areas of the world where infectious diseases and malnutrition are important causes of death early in life, the beneficial effects of breast-feeding often outweigh the potential risk of HIV transmission through breast-feeding. Studies in such settings have shown that HIV-free survival at 7 months of age is similar in exposed infants that were breast-fed or formula-fed from birth [360–362]. Studies in Africa show that mothers who exclusively breast-feed in the first 6 months of life have reduced risk of HIV transmission compared with mothers who supplement breast-feeding with other foods and milk sources [360,361,363]. In areas of the world where the burden of infectious diseases and malnutrition is high and where alternatives to breast milk that provide adequate nutrition are unacceptable, affordable, feasible, and safe, exclusive breast-feeding is recommended by the WHO and other authorities for women whose HIV status is unknown and for women known to be HIV-infected [293,344,358,364]. The WHO policy also stresses the need for continued support for breast-feeding

by mothers who are HIV-negative, improved access to HIV counseling and testing, and government efforts to ensure uninterrupted access to nutritionally adequate human milk substitutes [344].

### Human T-Lymphotropic Viruses 1 and 2

HTLV-1 is endemic in Japan, the Caribbean, and parts of South America. This infection can be transmitted from mother to infant, and transmission occurs primarily through breast-feeding. HTLV-2 infection has been identified in some Native Americans and Native Alaskans and in some injection drug abusers in the United States and Europe. Mother-to-infant transmission of HTLV-2 has been shown, although the frequency with which this occurs and the route of transmission are uncertain. Women in the United States who are known to be seropositive for HTLV-1 or HTLV-2 should not breast-feed. Routine screening for HTLV-1 and HTLV-2 is not recommended [344].

### Rubella

Rubella virus has been recovered from milk after natural and vaccine-associated infection. It has not been associated with significant disease in infants, although transient seroconversion has been frequently shown. No contraindication to breast-feeding exists in women recently immunized with currently licensed rubella vaccines.

### West Nile Virus Infection

The RNA of West Nile virus has been detected in human milk, and seroconversion in breast-feeding infants also has been observed. Although West Nile virus can be transmitted in milk, the extent of transmission in humans remains to be determined. Most infants and children infected with the virus to date have been asymptomatic or have had minimal disease [344]. Because the risk is uncertain, the AAP recommends that women in endemic areas may continue to breast-feed.

## CURRENT TRENDS IN BREAST-FEEDING

International and national organizations have endorsed breast-feeding as the optimal means of feeding for healthy term infants [344]. The percentage of mothers initiating breast-feeding in developing countries generally is 80% or greater and often 90% or greater. The health and economic consequences for bottle-fed infants in these countries are severe, however. In the United States, at one point in the early 1970s, the rate of breast-feeding initiation was 25%. The rate of initiation since that time has increased but fluctuated over time. In a survey (IFPS II) conducted by the FDA in 2005-2007, 83% of respondents initiated breast-feeding [365].

In contrast to this favorable trend, the recommendation for exclusive breast-feeding for the first 6 months of life in the United States and internationally is uncommonly followed. In the United States, supplemental feeding was often initiated in the hospital in the immediate postpartum period, and by 3 months of age more than 61% of infants had received formula [365]. Similarly, although breast-feeding initiation approaches 100% in developing nations in Africa, Asia, and the Caribbean, the rates of exclusive breast-feeding for the first 6 months of life are approximately 50% and approximately 30% for infants less than 2 months and 2 to 5 months of age [1].

Within the United States, various demographic patterns seem to be associated with breast-feeding behavior. Older mothers, mothers with a college education, and mothers with higher incomes all are more likely to breast-feed. African American and Hispanic mothers, mothers of lower socioeconomic status who are participants in the Women, Infants, and Children (WIC) program of the U.S. Department of Health and Human Services, and mothers who live in the southern regions of the United States are much less likely to breast-feed. The low rate of breast-feeding for mothers enrolled in WIC is of particular concern because that agency has a specific policy to encourage breast-feeding. Many states now depend on formula manufacturer rebates to fund part of their WIC programs, however, creating a conflict of interest. The disturbing part of the demographic pattern of breast-feeding in the United States is that the infants of lower socioeconomic status mothers, who would accrue the greatest health and economic benefits from breast-feeding, are those least likely to be breast-fed.

Although demographic studies indicate who is breast-feeding, they do not explain the behavioral differences among groups of mothers. One of the more complete models designed to explain breast-feeding behavior includes components that address maternal attitudes and family, societal, cultural, and environmental variables [366]. Individual studies have shown that the maternal decision-making process is closely related to the social support and influence that come from the family members surrounding the mother [367]. The husband in particular seems to have a strong positive influence, whereas the mother's mother may have a negative influence on the breast-feeding decision. Social support seems to be different among ethnic groups, as are maternal attitudes; such differences may provide one explanation for differences in breast-feeding behavior among ethnic groups [368,369]. Higher rates of exclusive breast-feeding have been observed for infants born in U.S. hospitals who follow the practices recommended by the WHO/United Nations Children's Fund Baby-friendly Hospital Initiative, which emphasizes 10 steps that promote successful breast-feeding [370].

## SUMMARY AND CONCLUSIONS

Human milk contains a wide variety of soluble and cellular components with a diverse spectrum of biologic functions. The major milk components identified to date exhibit antimicrobial, anti-inflammatory, proinflammatory, and immunoregulatory functions; cytotoxicity for tumor cells; ability to repair tissue damage; receptor analogue functions; and other metabolic effects. The biologic activities of different milk components are summarized in Table 5–10.

Polymorphonuclear leukocytes, macrophages, lymphocytes, and epithelial cells are observed in human milk, but their functions in milk are unknown. It is possible that their primary task is the antimicrobial defense of the

**TABLE 5–10** Possible Role of Soluble and Cellular Factors Identified in Human Milk

| Factor | Antimicrobial | Anti-inflammatory | Proinflammatory | Immunoregulatory | Other |
|---|---|---|---|---|---|

*IL-1α, TNF-β, and IL-6 are associated with increased levels of leptin.*
*+ to +++ = minimal to moderate effect; — = no known effect; ± = equivocal.*
*IL, interleukin; PMNs, polymorphonuclear neutrophils; sIgA, secretory IgA; TGF, transforming growth factor; TLR, toll-like receptor; TNF, tumor necrosis factor.*

mammary gland itself. These cells may help to promote tolerance to their mothers' HLA allotype, which may have implications regarding immune responsiveness and allograft rejection [371].

The bulk of the antimicrobial effects of human milk are associated with milk immunoglobulin, especially the sIgA isotype, which makes up to 80% of all immunoglobulins in the human body. Milk antibodies seem to provide protection against many intestinal pathogens, such as *Campylobacter*, *Shigella*, *E. coli*, *V. cholerae*, *Giardia*, and rotavirus, and against respiratory pathogens such as respiratory syncytial virus. Milk antibodies also effectively neutralize toxins and various human viruses. The role of small amounts of IgG and IgM in milk is uncertain. Milk IgA antibodies generally induce antimicrobial protection in the absence of any inflammation. Lactoferrin, lysozyme, α-lactalbumin, and other milk proteins and carbohydrates and lipids also contribute to the antimicrobial and immunomodulatory properties of human milk. Milk also contains numerous cytokines, chemokines, growth factors, soluble TLRs, and CD14, which modulate inflammatory and immunologic responses in the gut.

The passive transfer of the diversity of maternal biologic experiences to the neonate through the process of breast-feeding represents an essential component of the survival mechanism in the mammalian neonate. For millions of years, maternal products of lactation delivered through the process of breast-feeding have been the sole source of nutrition and immunity during the neonatal period and early infancy for all mammals, including the human infant. During the past 150 to 300 years, human societies have undergone remarkable changes, which have had a major impact on the basic mechanisms of maternal-neonatal interaction, breast-feeding, and the environment. Such changes include introduction of sanitation and nonhuman milk and formula feeds for neonatal nutrition, use of antimicrobial agents, introduction of processed foods, and exposure to newer environmental macromolecules and dietary antigens. The introduction of such human-made changes in the neonatal environment has had a profound impact on human homeostatic mechanisms, while allowing new insights into the role of breast-feeding in the developing human neonate.

Comparative analysis of natural (traditional) forms of breast-feeding and artificial feeding modalities has shown that natural breast-feeding is associated with significant reduction in infant mortality and morbidity; protection

against acute infectious diseases; and possible protection against allergic disorders and autoimmune disease, acute and chronic inflammatory disorders, obesity, diabetes mellitus and other metabolic disorders, allograft rejection, and development of many malignant conditions in childhood or later in life. This information has been reviewed by Hanson in an elegant monograph [372] and by others [86]. Despite the overwhelmingly protective role attributed to natural breast-feeding and the evolutionary advantages related to the development of lactation, several infectious agents have acquired, during the course of evolution, the ability to evade immunologic factors in milk and to use milk as the vehicle for maternal-to-infant transmission. The potential for the acquisition of infections, including HIV, HTLV, CMV, and possibly other pathogens, highlights potential hazards of breast-feeding in some clinical situations. It is reasonable to conclude that the development of lactation, the hallmark of mammalian evolution, is designed to enhance the survival of the neonate of the species and that breast-feeding may have a remarkable spectrum of immediate and long-term protective functions.

CHAPTER 6

# Bacterial Sepsis and Meningitis

Victor Nizet ✪ Jerome O. Klein

## CHAPTER OUTLINE

Bacterial sepsis in the neonate is a clinical syndrome characterized by systemic signs of infection and accompanied by bacteremia in the first month of life. Meningitis in the neonate is usually a sequela of bacteremia and is discussed in this chapter because meningitis and sepsis typically share a common cause and pathogenesis. Infections of the bones, joints, and soft tissues and of the respiratory, genitourinary, and gastrointestinal tracts can be accompanied by bacteremia, but the cause, clinical features, diagnosis, and management of these infections are sufficiently different to warrant separate discussions. Bloodstream and central nervous system (CNS) infections caused by group B streptococci (GBS), *Staphylococcus aureus* and coagulase-negative staphylococci (CoNS), *Neisseria gonorrhoeae*, *Listeria monocytogenes*, *Salmonella* species, Treponema pallidum, and Borrelia borderforrii, and *Mycobacterium tuberculosis* are described in detail in individual chapters. Chapter 2 describes the features of neonatal sepsis and meningitis in developing regions of the world.

The two patterns of disease—early onset and late onset—have been associated with systemic bacterial infections during the first month of life (Table 6–1). Early-onset disease

**TABLE 6–1** Characteristics of Early-Onset and Late-Onset Neonatal Sepsis

| Characteristic | Early-Onset* | Late-Onset† |
|---|---|---|
| Time of onset (days) | 0-6 | 7-90 |
| Complications of pregnancy or delivery | + | ± |
| Source of organism | Mother's genital tract | Mother's genital tract; postnatal environment |
| Usual clinical presentation | Fulminant | Slowly progressive or fulminant |
| | Multisystem | Focal |
| | Pneumonia frequent | Meningitis frequent |
| Mortality rate (%) | 3-50‡ | 2-40‡ |

*Many studies define early-onset sepsis as sepsis that occurs in the first 72 hours of life; others define it as sepsis that occurs in the first 5 or 6 days of life.
†Very small premature infants may have late-onset sepsis beyond 90 days of life.
‡Higher mortality rates in earlier studies.

typically manifests as a fulminant, systemic illness during the first 24 hours of life (median age of onset approximately 6 hours), with most other cases manifesting on the second day of life. Infants with early-onset disease may have a history of one or more obstetric complications, including premature or prolonged rupture of maternal membranes, preterm onset of labor, chorioamnionitis, and peripartum maternal fever, and many of the infants are premature or of low birth weight. Bacteria responsible for early-onset disease are acquired hours or days before delivery from the birth canal during delivery after overt or occult rupture of membranes. The mortality rate varies from 3% to 50% in some series, especially with gram-negative pathogens.

Late-onset disease has been variably defined for epidemiologic purposes as occurring after 72 hours to 6 days (e.g., group B streptococcus) of life. Very late onset infection secondary to group B streptococcus (disease in infants >3 months old) is discussed in Chapter 12. Term infants with late-onset infections can have a history of obstetric complications, but these are less characteristic than in early-onset sepsis or meningitis. Bacteria responsible for late-onset sepsis and meningitis include organisms acquired from the maternal genital tract and organisms acquired after birth from human contacts or infrequently from contaminated hospital equipment or materials when prolonged intensive care is needed for a neonate. The mortality rate usually is lower than for early-onset sepsis but can range from 2% to 40%, with the latter figure typically for infants of very low birth weight with gram-negative sepsis.

Because different microorganisms are responsible for disease by age at onset, the choice of antimicrobial agents also differs. Some organisms, such as *Escherichia coli*, groups A and B streptococci, and *L. monocytogenes*, can be responsible for early-onset and late-onset infections, whereas others, such as *S. aureus*, CoNS, and *Pseudomonas aeruginosa*, rarely cause early-onset disease and typically are associated with late-onset disease. The survival of very low birth weight infants with prolonged stays in the neonatal intensive care unit (NICU) has been accompanied by increased risk for nosocomial or hospital-associated infections and for very late onset disease (see Chapter 35) [1].

## BACTERIOLOGY

The changing pattern of organisms responsible for neonatal sepsis is reflected in a series of reports by pediatricians at the Yale–New Haven Hospital covering the period 1928-2003 (Table 6–2) [2–8]. Before development of the sulfonamides, gram-positive cocci including *S. aureus* and β-hemolytic streptococci caused most cases of neonatal sepsis. With the introduction of antimicrobial agents, gram-negative enteric bacilli, particularly *E. coli*, became the predominant cause of serious infection in the newborn. Reports for the periods 1966-1978 and 1979-1988 document the increase in importance of GBS and *E. coli* as agents of neonatal sepsis. In a more recent analysis from 1989-2003, CoNS species, predominantly *Staphylococcus epidermidis*, emerged as the most commonly identified agent of neonatal sepsis, with GBS, *E. coli*, *Enterococcus faecalis*, *S. aureus*, and *Klebsiella* species also occurring with substantial frequency. Later reports also document the problem of sepsis in very premature and low birth weight infants who have survived with the aid of sophisticated life-support equipment and advances in neonatal intensive care—CoNS are particularly threatening in these infants. Emerging data from the same center indicate that although intrapartum antibiotic prophylaxis protocols have reduced the overall incidence of early-onset sepsis, they may be influencing a higher proportion of septicemia attributable to ampicillin-resistant *E. coli* [9].

The etiologic pattern of microbial infection observed at Yale Medical Center also has been reported in studies of neonatal sepsis carried out at other centers during the same intervals (Table 6–3). Studies indicate that GBS and gram-negative enteric bacilli, predominantly *E. coli*, were the most frequent pathogens for sepsis, but other organisms were prominent in some centers. *S. aureus* was an important cause of sepsis in the mid-1980s in Finland [10] and East Africa [11] and a more recently significant pathogen in Connecticut [7] and southern Israel [12]. *S. epidermidis* was responsible for 53% of cases in Liverpool [13], and CoNS account for 35% to 48% of all late-onset sepsis in very low birth weight infants across the United States [14,15] and in Israel [16]. *Klebsiella* and *Enterobacter* species were the most common bacterial pathogens in Tel Aviv [17]. Sepsis and focal infections in neonates in developing countries are discussed further in Chapter 2.

A survey of five university hospitals in Finland [10] provides data about the association of the etiologic agent and mortality based on age at onset of sepsis (Table 6–4) and birth weight (Table 6–5). Infants with sepsis onset during the first 24 hours of life and weighing less than 1500 g at birth had the highest mortality rate.

The mortality rates for neonatal sepsis over time are documented in the Yale Medical Center reports. In the preantibiotic era, neonatal sepsis usually was fatal. Even with the introduction of penicillins and aminoglycosides in the reports from 1944-1965, death resulted from sepsis in most infants. Concurrent with the introduction of NICUs and technologic support for cardiorespiratory

and metabolic functions beginning in the early 1970s, the mortality rate was reduced to 16%. By 1989-2003, mortality from neonatal sepsis in this academic medical center was rare, occurring in only 3% of cases. A decline in the incidence of early-onset sepsis, commonly associated with more virulent pathogens, coupled with an increase in late-onset and "late-late" onset sepsis from CoNS and other commensal species (which together now account for nearly half of all cases), has contributed to the improved survival figures, along with continued advances in care and monitoring of critically ill infants.

The Yale data also provide information about the microorganisms responsible for early-onset and late-onset bacterial sepsis (Table 6–6). GBS were responsible for most early-onset disease. CoNS, *S. aureus*, *E. coli*, *Enterococcus* species, and *Klebsiella* species were the major pathogens of late-onset disease; a wide variety of gram-positive cocci and gram-negative bacilli are documented as causes of bacterial sepsis in infants after age 30 days.

The incidence of neonatal sepsis showed a strong inverse correlation to birth weight in the latest Yale cohort: birth weight greater than 2000 g, 0.2%; 1500 to 1999 g, 2.5%; 1000 to 1499 g, 9.4%; 750 to 999 g, 14.8%; and less than 750 g, 34.8%. Survival of very low birth weight infants (<1500 g) has been accompanied by an increased risk for invasive, nosocomial, or health care–associated bacterial infection as a cause of morbidity and mortality. The danger of sepsis is documented in a multicenter trial that enrolled 2416 very low birth weight infants in a study of the efficacy of intravenous immunoglobulin in preventing nosocomial infections [18]. Of the very low birth weight infants, 16% developed septicemia at a median age of 17 days, with an overall mortality rate of 21% and hospital stay that averaged 98 days; infants without sepsis had an overall mortality rate of 9% and 58-day average length of stay. Stoll and colleagues [19] reported patterns of pathogens causing early-onset sepsis in very low birth weight infants (400 to 1500 g) in the centers participating in the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network. Compared with earlier cohorts, a marked reduction in group B streptococcal infections (from 5.9 to 1.7 per 1000 live births) and an increase in *E. coli* infections (3.2 to 6.8 per 1000 live births) were noted, although the overall incidence of neonatal sepsis in this population did not change.

Organisms responsible for bacterial meningitis in newborns are listed in Table 6–7, which summarizes data collected from 1932-1997 at neonatal centers in the United States [20–23], The Netherlands [24], Great Britain [25,26], and Israel [12]. Gram-negative enteric bacilli and GBS currently are responsible for most cases. Organisms that cause acute bacterial meningitis in older children and adults—*Streptococcus pneumoniae*, *Neisseria meningitidis*, and type b and nontypable *Haemophilus influenzae*—are relatively infrequent causes of meningitis in the neonate [27]. A nationwide survey of causative agents of neonatal meningitis in Sweden in 1976-1983 indicated a shift from bacterial to viral or unidentified microorganisms, with lower attributable mortality rates [28].

## GROUP B STREPTOCOCCI

Group B β-hemolytic streptococci were implicated in human disease shortly after the precipitin-grouping technique was described [29]. For the past 3 decades, GBS have been the most common organisms causing invasive disease in neonates throughout the United States and western Europe (see Chapter 12).

*Streptococcus agalactiae*, the species designation of GBS, has a characteristic colonial morphology on suitable solid media. The organism produces a mucoid colony with a narrow zone of β-hemolysis on sheep blood agar media. GBS can be differentiated immunochemically on the basis of their type-specific polysaccharides. Ten capsular types—Ia, Ib, II, III, IV, V, IV, VI, VII, and VIII—have been characterized, and most invasive human isolates can be classified as one of these types, with serotypes Ia, III, and V the most prevalent in many more recent epidemiologic surveys.

GBS have been isolated from various sites and body fluids, including throat, skin, wounds, exudates, stool, urine, cervix, vagina, blood, joint, pleural or peritoneal fluids, and cerebrospinal fluid (CSF). The organisms frequently are found in the lower gastrointestinal and genital tracts of women and men and in the lower gastrointestinal and upper respiratory tracts of newborns. Patterns of early-onset, late-onset, and very late onset disease have been associated with GBS (see Table 6–1). Early-onset disease manifests as a multisystem illness with rapid onset typically during the first 1 or 2 days of life and is frequently characterized by severe respiratory distress. The pathogenesis is presumed to be similar to that of other forms of early-onset sepsis of neonates. The mortality rate is currently estimated at 8%, but was 50% in the 1970s [30].

Clinical manifestations of late-onset neonatal sepsis are more insidious than the manifestations of early-onset disease, and meningitis is frequently a part of the clinical picture. Some infants with meningitis have a fulminant onset, however, with rapid progression to centrally mediated apnea. Many infants with late-onset sepsis are products of a normal pregnancy and delivery and have no problems in the nursery. It is uncertain whether group B streptococcal infection was acquired at the time of birth and carried until disease developed, was acquired after delivery from the mother or other household contacts, or

was acquired from other infants or personnel in the nursery. In late-onset infection, most strains belong to serotype III. The mortality rate, estimated at 3%, is lower than the mortality for early-onset disease. With increasing survival of extremely low birth weight (<1000 g) infants, very late onset disease (>89 days) has been described [16].

In addition to sepsis and meningitis, other manifestations of neonatal disease caused by GBS include pneumonia, empyema, facial cellulitis, ethmoiditis, orbital cellulitis, conjunctivitis, necrotizing fasciitis, osteomyelitis, suppurative arthritis, and impetigo. Bacteremia without systemic or focal signs of sepsis can occur. Group B streptococcal infection in pregnant women can result in peripartum infections, including septic abortion, chorioamnionitis, peripartum bacteremia, septic pelvic thrombophlebitis, meningitis, and toxic shock syndrome [31].

## GROUP A STREPTOCOCCI

Streptococcal puerperal sepsis has been recognized as a cause of morbidity and mortality among parturient women since the 16th century [32–36]. Neonatal group A

streptococcal infection now is reported infrequently [37–43], but it can occur rarely in epidemic form in nurseries [37,44–47]. The reemergence of virulent group A streptococcal infections during the last 3 decades, including invasive disease and toxic shock syndrome, has been reflected in more case reports of severe disease in pregnant women and newborns.

Group A streptococcal disease in the mother can affect the fetus or newborn in two clinical patterns. Maternal streptococcal bacteremia during pregnancy can lead to in utero infection resulting in fetal loss or stillbirth; alternatively, acquisition of group A streptococci from the maternal genital tract can cause early-onset neonatal sepsis similar to early-onset group B streptococcal disease. In the first form of disease, previously healthy pregnant women with influenza-like signs and symptoms have been reported. This presentation rapidly progressed to disseminated intravascular coagulopathy and shock, with high mortality and risk to the fetus or newborn [48–50].

The features of 38 cases of neonatal invasive group A streptococcal infection from the literature were catalogued in 2004 [51]. Overall mortality rate in neonatal invasive group A streptococcal infection was significantly high (31%). Most of these infants presented with early-onset infection (62%), with many occurring in the first 48 hours of life. A specific focus of group A streptococcal infection was documented in three quarters of cases—42% of neonates had pneumonia, sometimes complicated by empyema, and 17% had a toxic shock syndrome–like presentation. Among the cases of early-onset group A streptococcal infection, puerperal sepsis or toxic shock-like syndrome in the mother during the peripartum period was an associated factor in 62% of cases. In late-onset cases of neonatal group A streptococcal infection reviewed in this series, soft tissue infections, meningitis, and pneumonia were among the reported clinical manifestations. A review by Greenberg and colleagues [52] in 1999 on 15 cases of group A streptococcal neonatal infection yielded similar statistics on clinical presentations and mortality.

In addition to sepsis, meningitis, and toxin-mediated disease in the neonate, focal infections, including cellulitis, omphalitis, Ludwig angina [53], pneumonia, and osteomyelitis, have been reported. Because all group A streptococci are susceptible to β-lactam antibiotics, the current strategy for prevention or treatment of infections caused by GBS also could apply to infections caused by group A streptococci.

## *STREPTOCOCCUS PNEUMONIAE*

Although pneumococcal infections in the neonate are unusual occurrences, they are associated with substantial morbidity and mortality [54–61]. Bortolussi and colleagues [54] reported five infants with pneumococcal sepsis who had respiratory distress and clinical signs of infection on the first day of life. Three infants died, two within 12 hours of onset. *S. pneumoniae* was isolated from the vaginas of three of the mothers. Radiographic features were consistent with hyaline membrane disease or pneumonia or both. The clinical features were strikingly similar to features of early-onset group B streptococcal infection, including the association of prolonged interval after rupture of membranes, early-onset respiratory distress, abnormal chest radiographs, hypotension, leukopenia, and rapid deterioration. Fatal pneumococcal bacteremia in a mother 4 weeks postpartum and the same disease and outcome in her healthy term infant, who died at 6 weeks of age, suggested an absence of protective antibody in the mother and the infant [55].

Hoffman and colleagues from the United States Multicenter Pneumococcal Surveillance Group [59] identified 20 cases of neonatal *S. pneumoniae* sepsis or meningitis in a review of 4428 episodes of pneumococcal infection at eight children's hospitals from 1993-2001. Ninety percent of the infants were born at term, with a mean age at the onset of infection of 18.1 days. Only two of the mothers had clinically apparent infections at the time of delivery. Eight neonates had meningitis, and 12 had bacteremia; 4 of the bacteremic neonates also had pneumonia. The most common infecting pneumococcal serotypes were 19 (32%), 9 (18%), and 18 (11%). Penicillin and ceftriaxone nonsusceptibility were observed in 21.4% and 3.6% of isolates. Three deaths (15%) occurred, all within 36 hours of presentation. A case report of peripartum transmission of penicillin-resistant *S. pneumoniae* underlines concern that the increasing use of peripartum ampicillin to prevent group B streptococcal disease in neonates may result in an increase in neonatal infections caused by β-lactam–resistant organisms [60].

## OTHER STREPTOCOCCI

Human isolates of group C and G streptococci form large β-hemolytic colonies that closely resemble those of group A streptococcus and share many virulence genes, including genes encoding surface M proteins and the cytotoxin streptolysin S. Group C streptococci have been associated with puerperal sepsis, but neonatal sepsis or meningitis related to these organisms is rare [62–65]. Likewise, group G streptococci are an infrequent cause of neonatal sepsis and pneumonia [66–70]. Maternal intrapartum transmission was the likely source for most cases [68], and concurrent endometritis and bacteremia in the mother and sepsis in the neonate have been reported [69]. Dyson and Read [68] found very high rates of colonization in neonates born at New York Hospital in a 1-year survey of discharge cultures in 1979; the monthly incidence of cultures of group G streptococci from the nose and umbilicus ranged from 41% to 70%. During this period, group B streptococcal colonization was only 1% to 11% [68].

Viridans streptococci are a heterogeneous group of α-hemolytic and nonhemolytic streptococci that are constituents of the normal flora of the respiratory and gastrointestinal tracts of infants, children, and adults. There are several classification schemata for these streptococci, and they may bear different designations in the literature. *Streptococcus bovis* is capable of causing neonatal sepsis and meningitis that is clinically similar to sepsis caused by GBS [71–73]. Rare cases of neonatal sepsis caused by *Streptococcus mitis* have been reported [74,75].

Viridans streptococci accounted for 23% of isolates from cultures of blood and CSF obtained from neonates

at the Jefferson Davis Hospital, Houston; only GBS were more common (28%) as a cause of neonatal sepsis [76]. In this series, most infants had early-onset infection with clinical features similar to sepsis caused by other pathogens, but 22.6% had no signs of infection. One infant had meningitis. The case-fatality rate was 8.8%. Sepsis related to viridans streptococci also has been reported from Finland [10], Liverpool [13], Indianapolis [77], and Montreal [78]. Among ventilated neonates in a NICU in Ankara, Turkey, the most prominent bacteria in bronchioalveolar lavage cultures were multidrug-resistant viridans streptococci (66%), and these were also one of the most common bloodstream isolates (29%) in the same population [79]. It is clear from these studies that isolation of viridans streptococci from the blood culture of a neonate suspected to have sepsis cannot be considered a contaminant, as is the case in many other patient populations.

## *ENTEROCOCCUS* SPECIES

Members of the genus *Enterococcus* (*E. faecalis* and *Enterococcus faecium*) were formerly classified as group D streptococci; but in the mid-1980s, genomic DNA sequence analysis revealed that taxonomic distinction was appropriate, and a unique genus was established [80]. Enterococci are differentiated from nonenterococci by their ability to grow in 6.5% sodium chloride broth and to withstand heating at 60° C for 30 minutes.

Most cases of enterococcal sepsis in the neonate are caused by *E. faecalis*, with a smaller number caused by *E. faecium* [71,72,81–84]. In 4 years beginning in 1974, 30 neonates with enterococcal sepsis occurred among 30,059 deliveries at Parkland Memorial Hospital in Dallas [81]. During this period, enterococci were second only to GBS (99 cases) and were more common than *E. coli* (27 cases) as a cause of neonatal sepsis. The clinical presentation in most cases was similar to early-onset sepsis of any cause [83]. Among infants with respiratory distress as a prominent sign of infection, chest radiographs were similar to radiographs showing the hyaline membrane–appearing pattern of group B streptococcal infection. Enterococcal bacteremia during 10 years beginning in January 1977 was reported in 56 neonates from Jefferson Davis Hospital in Houston, Texas [85]. Early-onset disease was a mild illness with respiratory distress or diarrhea; late-onset infection often was severe with apnea, bradycardia, shock, and increased requirement for oxygen and mechanical ventilation; many cases were nosocomial [85]. A large series of 100 cases of enterococcal bacteremia in neonates over a 20-year period at New York Hospital–Cornell Medical Center was evaluated by McNeeley and colleagues [82]. The presence of a central venous catheter (77%) and a diagnosis of necrotizing enterocolitis (33%) were common characteristics.

*Enterococcus* species generally are resistant to cephalosporins and are only moderately susceptible to penicillin G and ampicillin; they require the synergistic activity of penicillin at high dosage and an aminoglycoside for maximal bactericidal action. Nonenterococcal strains are susceptible to penicillin G, ampicillin, and most cephalosporins. Vancomycin-resistant *Enterococcus* has been reported from NICUs, causing illnesses clinically indistinguishable from vancomycin-sensitive strains [82]; these resistant strains raise concerns about the efficacy of antimicrobial agents currently approved for use in neonates [86]. Use of high doses of ampicillin is one option, but other drugs, including the newer streptogramin combination of quinupristin and dalfopristin and the oxazolidinone, linezolid, may be suggested by the susceptibility pattern (see Chapter 37).

## *STAPHYLOCOCCUS AUREUS* AND COAGULASE-NEGATIVE STAPHYLOCOCCI

*S. aureus* and CoNS, especially *S. epidermidis*, colonize skin and mucosa. Isolation of *S. aureus* from tissue, blood, or other body fluid usually is clearly associated with disease. Most episodes of sepsis caused by *S. aureus* are hospital acquired, and mortality can be high (23% among 216 Swedish neonates with *S. aureus* bacteremia during the years 1967-1984), with low birth weight as the most important risk factor [87]. More recently, reports of pneumonia and other severe nosocomial infection in neonates caused by community-acquired methicillin-resistant *S. aureus* strains, including the epidemic USA300 clone, have been documented [88,89]. Molecular epidemiologic techniques have established direct transmission of community-acquired methicillin-resistant *S. aureus* between postpartum women [90] and among NICU patients [91].

CoNS include more than 30 different species. *S. epidermidis* is the dominant species of CoNS responsible for neonatal sepsis, but other species, including *Staphylococcus capitis*, *Staphylococcus hemolyticus* and *Staphylococcus hominis*, have been identified as causes of sepsis in newborns [92]. A well-documented increased incidence of CoNS sepsis [8,14–16,18] has accompanied the increased survival of very low birth weight and extremely low birth weight infants with developmentally immature immune systems and prolonged stay in NICUs. CoNS infections have been associated with the introduction of invasive procedures for maintenance and monitoring of the infants, in particular, long-term vascular access devices. Levels of serum complement and transplacental anti-CoNS IgG are inversely correlated with gestational age, and this relative deficiency in preterm infants contributes to their suboptimal opsonization and impaired bacterial killing of CoNS [93]. Because CoNS are present on the skin, isolation of these organisms from a single culture of blood can represent skin contamination, but also can indicate bloodstream invasion. Collection of two cultures of blood at separate sites can assist in differentiating skin or blood culture bottle contamination from bloodstream invasion in an infant with suspected late-onset sepsis [94], and adoption of a standard practice of two blood cultures can reduce the number of neonates diagnosed with CoNS and exposed to intravenous antibiotic therapy [95]. The significance of a positive blood culture yielding CoNS is discussed below in "Microbiologic Techniques."

Many episodes of sepsis caused by CoNS are associated with the use of vascular catheters. *S. epidermidis* and other CoNS species can adhere to and grow on surfaces of synthetic polymers used in the manufacture of catheters. Strains obtained from infected ventricular shunts or

intravenous catheters produce a mucoid substance (i.e., slime or glycocalyx) that stimulates adherence of microcolonies to various surfaces in the environment and on epithelial surfaces, ultimately leading to establishment of a biofilm [96,97]. In addition to this adhesin function, the slime may protect staphylococci against antibiotics and host defense mechanisms such as macrophage phagocytosis [98]. Parenteral nutrition with a lipid emulsion administered through a venous catheter with organisms adherent to the polymer provides nutrients for growth of the bacteria, leading to invasion of the bloodstream when the organisms reach an inoculum of sufficient size [99]. Disease in newborn infants caused by *S. aureus* and CoNS is discussed in detail in Chapter 14.

## *LISTERIA MONOCYTOGENES*

The potential of *L. monocytogenes* to contaminate food products and the resultant danger to immunocompromised patients and pregnant women was reconfirmed in a 2002 outbreak involving 46 patients in eight states. This outbreak resulted in seven deaths of adults and miscarriages or stillbirths in three pregnant women [100]. *Listeria* can be found in unprocessed animal products, including milk, meat, poultry, cheese, ice cream, and processed meats, and on fresh fruits and vegetables. The organism possesses several virulence factors that allow it to infect the fetal placental unit, survive and replicate within human cells, and achieve cell-to-cell spread [101]. Although most people exposed to *L. monocytogenes* do not develop illness, pregnant women can suffer fetal loss, and neonates can develop early-onset or late-onset sepsis and meningitis. Neonatal disease resulting from *Listeria* is discussed in detail in Chapter 13.

## *ESCHERICHIA COLI*

*E. coli* is second only to GBS as the most common cause of early-onset and late-onset neonatal sepsis and meningitis [9,102–104]. Coliform organisms are prevalent in the maternal birth canal, and most infants are colonized in the lower gastrointestinal or respiratory tracts during or just before delivery. The antigenic structure of *E. coli* is complex; members of this species account for more than 145 different somatic (O) antigens, approximately 50 flagellar (H) antigens, and 80 different capsular (K) antigens. Although there is a wide genetic diversity of human commensal isolates of *E. coli*, strains causing neonatal pathology are derived from a limited number of clones [105]. One of these, the O18:K1:H7 clone, is distributed globally, whereas others such as O83:K1 and O45:K1 are restricted to a smaller subset of countries [106]. The presence of a 134-kDa plasmid encoding iron aquisition systems and other putative virulence genes is characteristic of several of these clones, and loss of the plasmid reduces the virulence more than 100-fold in a neonatal rat model of *E. coli* meningitis [107].

The K1 capsular antigen present in certain strains of *E. coli* is uniquely associated with neonatal meningitis [108–110]. K1 antigen is polysialic acid that is immunochemically identical to the capsular antigen of group B *N. meningitidis*. McCracken and coworkers [109] found K1 strains in the blood or CSF of 65 of 77 neonates with meningitis related to *E. coli*. These strains also were cultured from the blood of some infants (14 of 36) and adults (43 of 301) with sepsis, but without meningitis. The K1 capsular antigen was present in 88% of 132 strains from neonates with *E. coli* meningitis reported from The Netherlands [24]. Infants with meningitis caused by K1 strains had significantly higher mortality and morbidity rates than infants with meningitis caused by non-K1 *E. coli* strains [110]. The severity of disease was directly related to the presence, amount, and persistence of K1 antigen in CSF. Strains of *E. coli* with K1 antigen were isolated from cultures of stool of 7% to 38% (varying with time and location of the study) of healthy newborns and from approximately 50% of nurses and mothers of the infants [110,111]. The K1 strains have been present in the birth canal of mothers and subsequently in cultures from their newborns, indicating that these newborn infants acquired the organisms vertically from their mothers [111,112]. High rates of carriage of K1 strains by nursery personnel indicate, however, that postnatal acquisition of the K1 strains in the nursery also may occur [110,111].

The pathogenesis of *E. coli* K1 infection is hypothesized to begin with bacterial penetration of the gastrointestinal epithelium to enter the circulation, and efficient transcytosis of gastrointestinal epithelial cell monolayers by the pathogen has been shown in tissue culture [113]. Next the organisms can establish high-grade bacteremia in the immunosusceptible neonate through the complement resistance properties of its *O*-lipopolysaccharide and K1 capsule–mediated impairment of opsonophagocytic killing [114]. Finally, the pathogen possesses a series of surface protein determinants (e.g., OmpA, IbeA-C, CNF1) that mediate binding to and invade brain endothelial cells, as shown in human tissue culture experiments and the neonatal rat model of meningitis [115].

## *KLEBSIELLA* SPECIES

*Klebsiella* is a genus of Enterobacteriaceae that has emerged as a significant nosocomial pathogen in neonates [116,117]. The four recognized species include *Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Klebsiella terrigena*, and *Klebsiella planticola*. *K. pneumoniae*, the most common human pathogen, and *K. oxytoca* cause neonatal infections of the bloodstream, urinary tract, CNS, lung, skin, and soft tissues [118–120]. Previously thought to be a nonpathogenic organism inhabiting soil and water, *K. planticola* has been implicated as a cause of neonatal sepsis [121,122].

In a 4-year retrospective study from Israel [123], *Klebsiella* species caused 31% of late-onset neonatal sepsis. *Klebsiella* was also the most common single agent in a review of sepsis in Jamaican neonates [124]. Greenberg and colleagues [12] performed an 8-year prospective study of neonatal sepsis and meningitis at Soroka University Medical Center during 1986-1994; 49 (20%) of 250 cases were caused by *K. pneumoniae*, with a mortality rate of 29%. Risk factors for infection included prematurity, very low birth weight, prolonged rupture of membranes (>24 hours), and cesarean section or instrument delivery. *Klebsiella* species seem to be common causes of liver abscess complicating bacteremia in neonates [125].

The reservoirs for transmission of *Klebsiella* infections include the hands of health care workers and the gastrointestinal tracts of hospitalized infants. Multidrug resistance, in the form of extended-spectrum β-lactamase production, of *Klebsiella* strains causing neonatal infections and nursery outbreaks has become a substantial problem in some nurseries and is associated with increased morbidity and mortality [126–128]. Enhanced infection control measures and changes in use of routine broad-spectrum antibiotics can reduce the frequency of these serious infections.

## *ENTEROBACTER* SPECIES

Among the *Enterobacter aerogenes* (i.e., *Aerobacter aerogenes*) species, *Enterobacter cloacae*, *Enterobacter sakazakii*, and *Enterobacter hormaechei* have caused sepsis and a severe form of necrotizing meningitis in neonates [129–134]. In 2008, the taxonomy of *E. sakazakii* was revised, resulting in identification of five species belonging to a new genus, *Cronobacter* [135]. For purposes of this chapter, the discussion of earlier articles retains the designation of *E. sakazakii*.

*Enterobacter* septicemia was the most common nosocomial infection in neonates at the Ondokuz Mayis University Hospital in Samsun, Turkey, from 1988-1992 [136]. Willis and Robinson [130] reviewed 17 cases of neonatal meningitis caused by *E. sakazakii*; cerebral abscess or cyst formation developed in 77% of the infants, and 50% of the infants died. Bonadio and colleagues [131] reviewed 30 cases of *E. cloacae* bacteremia in children, including 10 infants younger than 2 months. The high frequency of multidrug resistance among isolates from patients in the NICUs was attributed to routine extended-spectrum cephalosporin usage [137]. An outbreak of *E. sakazakii* in a French NICU in 1994 involved 17 cases including 7 neonates with necrotizing enterocolitis, 1 case of sepsis, and 1 case of meningitis; 8 infants were colonized, but asymptomatic; there were 3 deaths. Four separable pulse types of *E. sakazakii* were identified, but the deaths were attributable to only one [138]. In a review of *Enterobacter* sepsis in 28 neonates from Taiwan, thrombocytopenia (66%) and increased band-form neutrophils (41%) were common laboratory features, with a reported clinical outcome of 11% mortality, 14% meningitis, and 7% brain abscess [139].

In addition to the gastrointestinal tracts of hospitalized infants and hands of health care personnel, sources and modes of transmission of *Enterobacter* infections in the neonate include contaminated infant formula [140–143], contaminated total parenteral nutrition fluid [144,145], bladder catheterization devices [144], and contaminated saline [146]. Effective infection control measures require reinforcement of procedures including proper hand hygiene, aseptic technique, isolation protocols, and disinfection of environmental surfaces.

## *CITROBACTER* SPECIES

Organisms of the genus *Citrobacter* are gram-negative bacilli that are occasional inhabitants of the gastrointestinal tract and are responsible for disease in neonates and debilitated or immunocompromised patients. The genus has undergone frequent changes in nomenclature, making it difficult to relate the types identified in reports of newborn disease over the years. In 1990, *Citrobacter koseri* replaced *Citrobacter diversus* [147]. For the purposes of this chapter, *C. koseri* replaces *C. diversus*, even though the original article may refer to the latter name.

*Citrobacter* species are responsible for sporadic and epidemic clusters of neonatal sepsis and meningitis, and *C. koseri* is uniquely associated with brain abscesses [147–155]. Neonatal disease can occur as early-onset or late-onset presentations. Brain abscesses caused by *C. koseri* have been reported in a pair of twins [156]. Doran [147] reviewed outbreaks of *C. koseri* in NICUs resulting in sepsis and meningitis, septic arthritis, and skin and soft tissue infections. Other focal infections in neonates caused by *Citrobacter* species include bone, pulmonary, and urinary tract infections [147].

During the period 1960-1980, 74 cases of meningitis caused by *Citrobacter* species were reported to the Centers for Disease Control and Prevention (CDC) of the U.S. Public Health Service [148]. In 1999, Doran [147] reviewed an additional 56 cases of neonatal meningitis caused by *Citrobacter* species. Combining results from the two studies, brain abscess developed in 73 (76%) of 96 patients for whom information was available. The pathogenesis of brain abscess caused by *C. koseri* is uncertain; cerebral vasculitis with infarction and bacterial invasion of necrotic tissues is one possible explanation [153]. Studies in the neonatal rat model suggest that the ability of *C. koseri* to survive phagolysosome fusion and persist intracellularly within macrophages could contribute to the establishment of chronic CNS infection and brain abscess [157]. Such persistence of *C. koseri* in the CNS is well illustrated by a case report of recovery of the organism from CSF during a surgical procedure 4 years after treatment of neonatal meningitis [152]. The mortality rate for meningitis resulting from *Citrobacter* species was about 30%; most of the infants who survived had some degree of mental retardation. A review of 110 survivors of meningitis caused by *Citrobacter* revealed only 20 infants who were believed to have structurally intact brains and age-appropriate development [147].

*Citrobacter* species usually are resistant to ampicillin and variably susceptible to aminoglycosides. Historically, most infants were treated with a combination of penicillin or cephalosporin plus an aminoglycoside. Surgical drainage has been used in some cases with variable success. Choosing antimicrobial agents with the most advantageous susceptibility pattern and selected surgical drainage seems to be the most promising approach to therapy, but no one regimen has been found to be more successful than another. Plasmid profiles, biotypes, serotypes, and chromosomal restriction endonuclease digests are useful as epidemiologic markers for the study of isolates of *C. koseri*. Morris and colleagues [154] used these markers to investigate an outbreak of six cases of neonatal meningitis caused by *C. koseri* in three Baltimore hospitals from 1983-1985. Identification of a specific outer membrane protein associated with strains isolated from CSF but uncommon elsewhere can provide a marker for virulent strains of *C. koseri* according to some investigators [155].

## *SERRATIA MARCESCENS*

Similar to other members of Enterobacteriaceae, *Serratia marcescens* increasingly is associated with hospital-acquired infections in infants in the NICU [158–160]. Late-onset sepsis has occurred in infants infected from health care equipment [160–163], the hands of heath care workers [164], milk bottles [159], aqueous solutions such as theophylline [159], hand hygiene washes [160], and lipid parenteral feeds [162]. The gastrointestinal tracts of hospitalized infants provide a reservoir for transmission and infection [161]. Investigation of an outbreak of multidrug-resistant *S. marcescens* in the NICU identified exposure to inhalational therapy as an independent risk factor for acquisition [165].

In a review by Campbell and colleagues [166] of neonatal bacteremia and meningitis caused by *S. marcescens*, 11 (29%) of 38 infants had meningitis as a complication of bacteremia. Mean gestational age was 28 weeks, and mean birth weight was 1099 g. All patients required mechanical ventilation, 90% had central venous catheters in situ, 90% had received prior antibiotics, 50% had a prior intraventricular hemorrhage, 40% had a hemodynamically significant patent ductus arteriosus treated medically or surgically, and 20% had necrotizing enterocolitis with perforation. All patients were treated for a minimum of 21 days with combination antimicrobial therapy that included a third-generation cephalosporin or a ureidopenicillin and an aminoglycoside, typically gentamicin. Three of 10 patients died. Four of the seven survivors developed severe hydrocephalus requiring ventriculoperitoneal shunt placement and had poor neurologic outcome. Poor neurologic outcome also was documented in a report of *S. marcescens* brain abscess resulting in multicystic encephalomalacia and severe developmental retardation [167].

## *PSEUDOMONAS AERUGINOSA*

*P. aeruginosa* usually is a cause of late-onset disease in infants who are presumably infected from their endogenous flora or from equipment, aqueous solutions, or occasionally the hands of health care workers. An outbreak of *P. aeruginosa* sepsis in a French NICU was associated with contamination of a milk bank pasteurizer [168]. Stevens and colleagues [169] reported nine infants with *Pseudomonas* sepsis, four of whom presented in the first 72 hours of life. In three of these infants, the initial signs were of respiratory distress, and chest radiographs were consistent with hyaline membrane disease. Noma (i.e., gangrenous lesions of the nose, lips, and mouth) in a neonate has been associated with bacteremia caused by *P. aeruginosa* [170].

A retrospective review of sepsis in infants admitted over the 10-year period 1988-1997 to the NICU at Children's Hospital of the King's Daughters in Norfolk, Virginia, identified 825 cases of late-onset sepsis [14]. Infants with *Pseudomonas* sepsis had the highest frequency of clinically fulminant onset (56%), and 20 of the 36 (56%) infants with *Pseudomonas* sepsis died within 48 hours of collection of blood culture.

*P. aeruginosa* conjunctivitis in the neonate is a danger because it is rapidly destructive to the tissues of the eye and because it may lead to sepsis and meningitis. Shah and Gallagher [171] reviewed the course of 18 infants at Yale–New Haven Hospital NICU who had *P. aeruginosa* isolated from cultures of the conjunctiva during 10 years beginning in 1986. Five infants developed bacteremia, including three with meningitis, and two infants died. A cluster of four fatal cases of *P. aeruginosa* pneumonia and bacteremia among neonates in 2004 was traced by genotypic fingerprinting to their shared exposure to a health care worker experiencing intermittent otitis externa [172].

## *SALMONELLA* SPECIES

Non-Typhi *Salmonella* infection is an uncommon cause of sepsis and meningitis in neonates, but a significant proportion of cases of *Salmonella* meningitis occur in young infants. The CDC observed that approximately one third of 290 *Salmonella* isolates from CSF reported during 1968-1979 were from patients younger than 3 months, and more than half were from infants younger than 1 year [173]. A 21-year review of gram-negative enteric meningitis in Dallas beginning in 1969 identified *Salmonella* as the cause in 4 of 72 cases [23]. Investigators from Turkey reported seven cases of neonatal meningitis caused by *Salmonella* during the years 1995-2001 [174]. Two of the five survivors developed communicating hydrocephalus, and one had a subdural empyema. In a case of neonatal meningitis caused by *Salmonella enterica* serotype Agona, the pathogen was isolated simultaneously from the newborn's CSF, parental fecal samples, and the mother's breast milk [175].

Reed and Klugman [176] reviewed 10 cases of neonatal typhoid that occurred in a rural African hospital. Six of the infants had early-onset sepsis with acquisition of the organism from the maternal genital tract, and four had late-onset infection with acquisition from a carrier or an environmental source. Two neonates developed meningitis, and three died.

## *NEISSERIA MENINGITIDIS*

Although *N. meningitidis* is a leading cause of bacterial sepsis and meningitis among children and adolescents, it rarely is associated with invasive infection in neonates [12, 26, 177]. *N. meningitidis* may colonize the female genital tract [178–180] and has been associated with pelvic inflammatory disease [181]. The infant can be infected at delivery by organisms present in the maternal genital tract, or intrauterine infection can result during maternal meningococcemia [182]. Meningococcal sepsis is rare in neonates, but more than 50 cases (including 13 from the preantibiotic era) have been described [183–185]. Early-onset and late-onset forms [178, 179, 185] of meningococcal sepsis in neonates have been reported. Purpura similar to meningococcemia in older children has been observed in a 15-day-old infant [186] and a 25-day-old infant [187].

Shepard and colleagues [185] from the CDC reported 22 neonates with invasive meningococcal disease from a 10-year active, population-based surveillance of 10 states with diverse populations and more than 31 million persons. The average annual incidence was 9 cases per 100,000 people (versus 973.8 per 100,000 for GBS). Sixteen patients had meningitis, and 6 of these also had

meningococcemia. Six patients had early-onset disease. The overall mortality rate was 14%. Ten isolates were serogroup B, four were serogroup C, three were serogroup Y, one was nongroupable, and four were unavailable. A case of meningococcal meningitis in a 2-week-old infant was successfully treated with no evidence of neurologic sequelae [188].

## *HAEMOPHILUS INFLUENZAE*

Because of the introduction of *H. influenzae* type b conjugate vaccines in 1988, there has been a substantial decrease in the incidence in *H. influenzae* type b disease in infants and children in the United States and many other countries [189–191]. Given the estimated proportion of individuals who are completely immunized, the decrease in *H. influenzae* type b invasive disease has exceeded expectations. The reduction in *H. influenzae* carriage associated with vaccination and the consequent decreased transmission from immunized children to unimmunized infants and children likely explains this effect [192–194].

Despite increased reporting of invasive infections caused by nontypable *H. influenzae* in adults and older children [195–197], such infections in neonates remain uncommon [198–201]. Five clinical syndromes have been associated with neonatal disease caused by *H. influenzae*: (1) sepsis or respiratory distress syndrome, (2) pneumonia, (3) meningitis, (4) soft tissue or joint infection, and (5) otitis media or mastoiditis. The overall mortality rate was 5.5% for 45 cases reviewed by Friesen and Cho [202]; the mortality rate was 90% for 20 infants with a gestation lasting less than 30 weeks. Clinical and epidemiologic characteristics were similar to neonatal disease caused by GBS, including early-onset (≤24 hours of birth) and late-onset presentations, signs simulating respiratory distress syndrome, and a high mortality rate. Autopsy of infants with bacteremia related to nontypable *H. influenzae* and signs of respiratory distress syndrome revealed hyaline membranes with gram-negative coccobacilli within the membranes, similar to findings of hyaline membranes secondary to GBS [203].

Examination of placentas from mothers of infants with sepsis caused by nontypable *H. influenzae* revealed acute chorioamnionitis and acute villitis in some [199]. *H. influenzae* also has been responsible for maternal disease, including bacteremia, chorioamnionitis [204], acute or chronic salpingitis, and tubo-ovarian abscess [200]. A cluster of eight cases of early-onset infections over 53 months caused by β-lactamase–negative, nontypable *H. influenzae* was reported from an NICU in Israel [205]. In this series, a presentation resembling pneumonia rather than classic respiratory distress syndrome characterized the infants' respiratory problems. Neonatal sepsis caused by *Haemophilus parainfluenzae* [206–208] and *Haemophilus aphrophilus* [209] has been reported.

## ANAEROBIC BACTERIA

Improvements in techniques for isolation and identification of the various genera and species of anaerobic bacteria have provided a better understanding of the anaerobic flora of humans and their role in disease [210]. With the exception of *Clostridium tetani* and *Clostridium botulinum*, all of the anaerobic bacteria belong to the normal flora of humans. Anaerobes are present on the skin, in the mouth, in the intestines, and in the genital tract. They account for the greatest proportion of the bacteria of the stool. All are present in the intestines and have been isolated from the external genitalia or vagina of pregnant and nonpregnant women [211–213]. Newborns are colonized with these organisms during or just before delivery. A review of the literature on neonatal bacteremia caused by anaerobic bacteria by Brook [214] in 1990 included 179 cases, with a mortality rate of 26%. *Bacteroides* and *Clostridium* species were the most common isolates. Predisposing factors for infection included premature rupture of membranes, preterm delivery, and necrotizing enterocolitis.

Anaerobic bacteria have been isolated from the blood of newborns with sepsis [212,215,216], from various organs at autopsy [217], from an infant with an adrenal abscess [218], from an infant with an infected cephalhematoma [219], and from infants with necrotizing fasciitis of the scalp associated with placement of a scalp electrode [220]. Feder [221] reviewed meningitis caused by *Bacteroides fragilis*; seven of nine reported cases occurred in neonates.

The incidence of neonatal sepsis caused by anaerobic bacteria is uncertain, but more recent data available from surveys suggest the incidence is low (<5%) [12,14,214]. Noel and colleagues [215] identified 29 episodes of anaerobic bacteremia in neonates in the intensive care unit at New York Hospital during 18 years. Chow and coworkers [217] analyzed 59 cases of neonatal sepsis associated with anaerobic pathogens and classified them into four groups: (1) transient bacteremia after premature rupture of membranes and maternal amnionitis, (2) sepsis after postoperative complications, (3) fulminant septicemia (in the case of clostridial infections), and (4) intrauterine death associated with septic abortion. The mortality rate associated with neonatal anaerobic sepsis reported in the literature ranges from 4% to 38% [217,222,223].

Serious infections of the bloodstream or CNS of neonates caused by *Bacillus cereus* have been reported [224,225] and in certain cases have proven intractable and refractory to antibiotic therapy [226,227]. One outbreak of *B. cereus* infections in an NICU was traced to contamination of balloons used in mechanical ventilation [228]. *B. fragilis* has been identified as a cause of pneumonia, sepsis, or meningitis in the immediate newborn period [229–231].

Infections caused by *Clostridium* species can be localized, as in the case of omphalitis [232], cellulitis, and necrotizing fasciitis [233], or can manifest as sepsis or meningitis [234]. Disease in neonates has been related to *Clostridium perfringens*, *Clostridium septicum*, *Clostridium sordellii*, *Clostridium butyricum*, *Clostridium tertium*, and *Clostridium paraputrificum* [235]. The presenting signs usually are similar to signs of other forms of bacterial sepsis. Chaney [234] reported a case of bacteremia caused by *C. perfringens* in a mother and neonate in which the neonate had classic features of adult clostridial sepsis, including active hemolysis, hyperbilirubinemia, and hemoglobinuria. Motz and colleagues [236] reviewed five

cases of clostridial meningitis resulting from *C. butyricum* and *C. perfringens*. Clostridial sepsis has a high mortality rate [234].

## NEONATAL TETANUS

Neonatal tetanus is caused by the gram-positive anaerobic spore-forming bacillus *C. tetani*. The organism is present in soil and can be present in human and animal feces. Infection usually occurs after contamination of the umbilical stump. Maternal and neonatal tetanus are important causes of mortality in developing countries, resulting in an estimated 180,000 deaths annually [237]. In the United States, tetanus in the newborn is exceedingly rare [238]. Since 1984, only three cases of neonatal tetanus have been reported [238–240]. The most recent case, reported from Montana in 1998, was an infant born to an unimmunized mother; the parents used a *C. tetani*–contaminated clay powder to accelerate drying of the umbilical cord. The use of this product had been promoted on an Internet site on "cord care" for use by midwives [241].

In many developing countries, the incidence and mortality of neonatal tetanus remain startlingly high [242–245]. Mustafa and colleagues [246] conducted a retrospective neonatal tetanus survey among rural and displaced communities in the East Nile Province in the Sudan and observed an incidence of neonatal tetanus of 7.1 cases per 1000 live births, more than double that reported from the stable rural community (3.2 per 1000). In both communities, coverage with two doses of tetanus toxoid was about 58%. Mortality attributable to neonatal tetanus in Djakarta in 1982 was 6.9 deaths per 1000 live births, and in the island provinces of Indonesia, it was 10.7 deaths per 1000 live births [247]. Among 62 cases of neonatal tetanus in Ethiopia, 90% were born at home, and 70% lacked antenatal care [245]. Three quarters of infants in this series died in the hospital, and risk factors for fatal outcome included an incubation period of less than 1 week, onset of symptoms less than 48 hours, tachycardia, and fever [245]. The mortality rate for neonates with tetanus in Lima, Peru, was 45% and was not improved with use of intrathecal tetanus antitoxin [248]. A meta-analysis of intrathecal therapy in tetanus suggested benefit in adults, but not in neonates [249].

Application of contaminated materials to the umbilical cord is associated with deep-rooted customs and rituals in developing countries. A case-control study to identify risk factors for neonatal tetanus in rural Pakistan identified application of ghee (i.e., clarified butter from the milk of water buffaloes or cows) to the umbilical wound as the most important risk factor [250]. Although commercial ghee is available in Pakistan, the ghee used in rural areas is made at home from unpasteurized milk. Oudesluys-Murphy [251] observed that application of some materials, including ghee and a stone wrapped in wet cloth, increased the risk of neonatal tetanus among Yoruba women, but that other practices of cord care decreased the incidence, including searing of the cord with heat in China during the Ming dynasty and use of a candle flame to scar the cord in Guatemala. Neonatal tetanus is a preventable disease; use of hygienic techniques at delivery and a program of tetanus toxoid immunization of children and young adults, particularly of pregnant women, are effective in eliminating this lethal disease [251–254].

## MIXED INFECTIONS

Multiple organisms frequently are present in brain, liver, or lung abscesses; aspirates in the lung after pneumonia; or pleural empyema. Such mixed infections infrequently are found in cultures of the blood or CSF, however. When several species are found, the significance of each is uncertain because it is possible that one or more of the organisms in a mixed culture is a contaminant.

Bacteremia with more than one organism occurs in patients with immunodeficiency, major congenital abnormalities, or contamination of a body fluid with multiple organisms, as is present in peritonitis typically as a sequela of severe necrotizing enterocolitis in a very low birth weight infant. Neonatal meningitis caused by *S. pneumoniae* and *Acinetobacter calcoaceticus* [255] and sepsis caused by *P. aeruginosa* and *Yersinia enterocolitica* [256] have been reported. Although included in a series of cases of neonatal sepsis by some investigators, mixed cultures are not identified by most. Mixed infections were reported by Tessin and coworkers [257] in 5% of 231 Swedish neonates, by Vesikari and associates [258] in 4% of 377 Finnish infants, and by Bruun and Paerregaard [259] in 7% of 81 Danish neonates. Faix and Kovarik [260] reviewed the records of 385 specimens of blood or CSF submitted to the microbiology laboratories at the University of Michigan Medical Center for the period of September 1971 to June 1986. More than one organism was present in 38 specimens from 385 infants in the NICU; 15 (3.9%) infants had multiple pathogens associated with clinical signs of sepsis or meningitis. The mortality rate was high (60%).

Factors predisposing to mixed infection included prolonged rupture of membranes (>24 hours); total parenteral nutrition; necrotizing enterocolitis; presence of an intravascular catheter or ventriculostomy; and entities associated with multiple pathogens, including peritonitis, pseudomembranous colitis, and hepatic necrosis. Chow and colleagues [217] reported polymicrobial bacteremia in eight newborns with anaerobic coisolates or aerobic and anaerobic organisms in combination. Jarvis and associates [261] reported an outbreak of polymicrobial bacteremia caused by *K. pneumoniae* and *E. cloacae* associated with use of a contaminated lipid emulsion.

Mixed infections also can include bacteria and viruses or bacteria and fungi, typically *Candida*, in the situation of intravascular central catheter or peritoneal infections associated with bowel perforation. Sferra and Pacini [262] reported mixed viral-bacterial meningitis in five patients, including neonates with CSF isolates of enterovirus and GBS in a 10-day-old infant and enterovirus and *Salmonella* in a 12-day-old infant.

## UNCOMMON BACTERIAL PATHOGENS

Numerous additional bacterial pathogens have been identified as rare or uncommon causes of neonatal sepsis and meningitis. These are listed in Table 6–8 with their references and were reviewed by Giacoia [263].

**TABLE 6–8** Unusual Pathogens Responsible for Neonatal Sepsis and Meningitis

| Organism | Reference |
|---|---|
| *Achromobacter* species | 745-747 |
| *Acinetobacter* species | 748-752 |
| *Bacillus anthracis* | 753 |
| *Bacillus cereus* | 225, 226, 228, 754 |
| *Borrelia* (relapsing fever) | 755, 756 |
| *Brucella* species | 757, 758 |
| *Burkholderia cepacia* | 759-761 |
| *Burkholderia pseudomallei* | 762 |
| *Campylobacter* species | 718, 763 |
| *Capnocytophaga* species | 764-766 |
| *Corynebacterium* species | 767, 768 |
| *Edwardsiella tarda* | 769-771 |
| *Escherichia hermanii* | 772, 773 |
| *Chryseobacterium* (*Flavobacterium*) species | 774, 775 |
| *Gardnerella vaginalis* | 776, 777 |
| *Helicobacter cinaedi* | 778 |
| *Lactobacillus* species | 779, 780 |
| *Leptospira* species | 781, 782 |
| *Leuconostoc* species | 783, 784 |
| *Morganella morganii* | 785-787 |
| *Mycoplasma hominis* | 788 |
| *Ochrobactrum anthropi* | 789 |
| *Pantoea agglomerans* | 790 |
| *Pasteurella* species | 715, 791, 792 |
| *Plesiomonas* species | 793-795 |
| *Proteus mirabilis* | 796-798 |
| *Pseudomonas pseudomallei* | 799 |
| *Psychrobacter immobilis* | 800 |
| *Ralstonia pickettii* | 801 |
| *Rothia dentocariosa* | 802 |
| *Shigella sonnei* | 803-805 |
| *Staphylococcus capitis* | 806 |
| *Stomatococcus mucilaginosus* | 807 |
| *Vibrio cholerae* | 808, 809 |
| *Yersinia enterocolitica* | 810, 811 |
| *Yersinia pestis* | 812 |

# EPIDEMIOLOGY

## INCIDENCE OF SEPSIS AND MENINGITIS

The reported incidence of neonatal sepsis varies from less than 1 to 8.1 cases per 1000 live births [12,116,123, 257,264–269]. A 2-year study of 64,858 infants from the Atlanta metropolitan area beginning in January 1982 (Table 6–9) reported an incidence of early-onset group B streptococcal disease of 1.09 per 1000 live births and an incidence of 0.57 per 1000 live births for late-onset disease [267]. The increased usage of intrapartum antibiotic prophylaxis for women with group B streptococcal colonization with or without other risk factors associated with neonatal group B streptococcal disease has been associated with a 70% reduction in the incidence of early-onset group B streptococcal sepsis to 0.44 per 1000 live births in 1999, a rate comparable to that of late-onset sepsis (see Chapter 12) [7].

The incidence of meningitis usually is a fraction of the number of neonates with early-onset sepsis. During the 8-year period 1986-1994 at the Soroka University Medical Center in southern Israel, Greenberg and colleagues [12] found incidences of neonatal bacterial sepsis of 3.2 cases per 1000 live births and of meningitis of 0.5 case per 1000 live births. Certain pathogens that cause bloodstream invasion, such as GBS, *E. coli*, and *L. monocytogenes*, are more likely to be accompanied by meningeal invasion than others (e.g., *S. aureus*). Meningitis is more frequent during the first month of life than in any subsequent period (see Table 6–6).

## CHARACTERISTICS OF INFANTS WHO DEVELOP SEPSIS

Host susceptibility, socioeconomic factors, obstetric and nursery practices, and the health and nutrition of mothers are important in the pathogenesis of neonatal sepsis and meningitis. Infants who develop sepsis, particularly early-onset disease, usually have a history of one or more risk factors associated with the pregnancy and delivery that significantly increase the risk for neonatal infection. These factors include preterm delivery or low birth weight, premature rupture of membranes (i.e., rupture before the onset of labor), prolonged time of rupture of membranes, maternal peripartum infection, septic or traumatic delivery, and fetal hypoxia.

**TABLE 6–9** Incidence and Mortality of Group B Streptococcal Disease by Birth Weight, Atlanta 1982-1983

| | | Early Onset | | Late Onset | |
|---|---|---|---|---|---|
| Birth Weight | Total Births | Cases/(Deaths) | Cases/1000 | Cases/(Deaths) | Cases/1000 |
| <1500 g | 835 | 5 (1) | 5.99 | 0 | 0 |
| 1500-2499 g | 4380 | 11 (2) | 2.51 | 6 (0) | 1.37 |
| >2500 g | 59,303 | 53 (5) | 0.89 | 23 (0) | 0.39 |

*Data from Schuchat A, et al. Population-based risk factors for neonatal group B streptococcal disease: results of a cohort study in metropolitan Atlanta. J Infect Dis 162:672, 1990.*

## Birth Weight

The factor associated most significantly with enhanced risk for bacterial sepsis and meningitis in neonates is low birth weight (see Tables 6–5 and 6–9) [12,18,270–272]. Infection is the most common cause of death in infants with very low birth weight [271,272]. With the exception of infection caused by GBS, it is unusual for a term infant to develop early-onset sepsis after an uneventful pregnancy and delivery. In a study in England and Wales, neonates weighing less than 2000 g at birth acquired meningitis six times more frequently than infants weighing more than 2000 g [26]. The lower the infant's birth weight, the higher is the incidence of sepsis (see Table 6–5). An Israeli study of 5555 very low birth weight infants documented the increased risk of late-onset sepsis with decreasing birth weight; late-onset sepsis occurred in 16.8% of neonates with a birth weight of 1250 to 1500 g, 30.6% of neonates weighing 1000 to 1249 g, 46.4% of neonates weighing 750 to 999 g, and 53% of neonates weighing less than 750 g at birth [16]. In a study of infants in Atlanta (see Table 6–9), the importance of birth weight was identified as a predisposing factor for development of early-onset and late-onset sepsis. If very low birth weight infants survived the first days of life, rates of sepsis decreased, but remained elevated [267]; 16% of 2416 infants with birth weights of 501 to 1500 g who were enrolled in a study sponsored by NICHD developed sepsis at a median of 17 days of age [18].

**TABLE 6–10** Relationship of Attack Rates and Fatalities of Neonatal Group B Streptococcal Early-Onset Disease to Perinatal Characteristics

| Characteristic | Attack Rate per 1000 Live Births | Mortality Rate (%) |
|---|---|---|
| Birth weight (g) | | |
| <1000 | 26 | 90 |
| 1001-1500 | 8 | 25 |
| 1501-2000 | 9 | 29 |
| 2001-2500 | 4 | 33 |
| >2500 | 1 | 3 |

## Risk Factors of Infant and Mother

The relative importance of other factors associated with systemic infection in the newborn is more difficult to define. In their prospective study of 229 infants with sepsis and meningitis, Greenberg and coworkers [12] found that certain conditions were common: 130 (57%) were premature (<37 weeks' gestation), 64 (28%) were delivered by cesarean section or instrumental delivery, 43 (19%) had an Apgar score of less than 7 at 5 minutes, and 27 (2%) had a prolonged (>24 hours) interval after rupture of maternal membranes. Investigators in Pakistan [273] found that maternal urinary tract infection, maternal fever, vaginal discharge, and vaginal examinations during labor were maternal factors significantly associated with neonatal early-onset sepsis, whereas low Apgar scores at birth and the need for endotracheal intubation were significant neonatal risk factors.

Attack rates for early-onset group B streptococcal sepsis in a study from Chicago [274] were affected by birth weight, duration of rupture of membranes, and occurrence of maternal peripartum fever. Infants with one or more of these perinatal risk factors had an attack rate of 8 per 1000 live births and a mortality rate of 33% compared with infants without such risk factors, who had an attack rate of 0.6 per 1000 live births and a mortality rate of 6% (Table 6–10).

Maternal fever during labor or after delivery suggests a concurrent infectious event in the mother and infant, but noninfectious events may be responsible for maternal fever. Use of epidural analgesia for pain relief during labor is associated with increases in maternal temperature. Intrapartum fever of more than 38° C (>100.4° F) occurred an average of 6 hours after initiation of epidural anesthesia in 14.5% of women receiving an epidural anesthetic compared with 1% of women not receiving an epidural agent; the rate of fever increased from 7% in women with labors of less than 6 hours to 36% in women with labors lasting longer than 18 hours. There was no difference in the incidence of neonatal sepsis in the infants born to 1045 women who received epidural analgesia (0.3%) compared with infants born to women who did not have epidural analgesia (0.2%) [275]. Fetal core temperature may be elevated during maternal temperature elevation, and increased temperature may be present transiently in the neonate after delivery.

## Ethnicity

The Collaborative Perinatal Research Study provides historical information on 38,500 pregnancies [276]; selected data for white and black women are presented in Table 6–11. Black women had a higher rate of premature rupture of membranes lasting more than 24 hours (21.4%) compared with white women (10.8%), black women had a higher rate of puerperal infection (4.1%) compared with white women (3.6%), and more black infants weighed less than 2500 g at birth (13.4%) compared with white infants (7.1%). More recent published data concur with the data observed 30 years ago. The National Center for Health Statistics reported continued

**TABLE 6–11** Selected Characteristics of Women, Their Pregnancies, and Newborns (NINDS 1972)*

| Characteristic | Percent with Characteristics: White Women | Percent with Characteristics: Black Women |
|---|---|---|
| Premature rupture of membranes: time from rupture to onset of labor (hr) | | |
| <8 | 70.9 | 56.7 |
| 8-23 | 18.3 | 21.9 |
| 24-48 | 5.4 | 11.7 |
| ≥49 | 5.4 | 9.7 |
| Puerperal infection | 3.6 | 4.1 |
| Type of delivery | | |
| Vaginal vertex | 91.7 | 92.4 |
| Vaginal breech | 3.3 | 2.6 |

*Data from Niswander KR, Gordon M. The women and their pregnancies. The Collaborative Perinatal Study of the National Institute of Neurological Diseases and Stroke. U.S. Department of Health, Education and Welfare Publication No. (NIH) 73-379. Washington, DC, U.S. Government Printing Office, 1972.*

disparities between blacks and whites in maternal and infant health indicators [277]. In 1996, significant differences were found between blacks and the general population in terms of neonatal mortality (9.6 deaths versus 4.8 deaths per 1000 live births), low birth weight (13% versus 7.4%), and severe complications of pregnancy (23 complications versus 14 complications per 100 deliveries). A review of the literature from 1966-1994 reported significantly increased rates of severe histologic chorioamnionitis, maternal fever during labor, prolonged rupture of membranes, and early neonatal mortality from sepsis in blacks compared with whites [278].

In a study of group B streptococcal disease in infants from the Atlanta metropolitan area [267], black infants had a higher incidence than nonblack infants of early-onset disease; the risk of late-onset disease was 35 times greater in black than in white infants. After controlling for other significant risk factors, such as low birth weight and maternal age younger than 20 years, 30% of early-onset disease and 92% of late-onset disease could be attributed to black race. The increased incidence of group B streptococcal disease in blacks of all ages was observed in a survey by the CDC in selected counties in California, Georgia, and Tennessee and the entire state of Oklahoma. The rate of disease of 13.5 cases per 100,000 blacks was significantly higher than the 4.5 cases per 100,000 whites. In neonates with early-onset infection, 2.7 cases per 1000 live births occurred in blacks, and 1.3 cases per 1000 live births occurred in whites [279]. Maternal factors such as socioeconomic status, nutrition, recently acquired sexually transmitted diseases, or racial

**TABLE 6–12** Incidence of Fetal and Neonatal Infections by Sex

| Infection | No. Infants: Male | No. Infants: Female | Ratio of Male to Female |

differences in maternally acquired protective antibodies may result in the increased risk of group B streptococcal disease among blacks.

## Gender

Historical data have suggested that there is a predominance of male neonates affected by sepsis and meningitis, but not by in utero infections (Table 6–12) [280,281]. This difference may partially reflect the fact that female infants had lower rates of respiratory distress syndrome (i.e., hyaline membrane disease) than male infants. Torday and colleagues [282] studied fetal pulmonary maturity by determining lecithin-to-sphingomyelin ratios and concentrations of saturated phosphatidylcholine and cortisol in amniotic fluid of fetuses of 28 to 40 weeks' gestation. Female infants had higher indices of pulmonary maturity than male infants. These data provide a biochemical basis for the increased risk of respiratory distress syndrome in male infants and the possible role of these factors of pulmonary maturation in the development of pulmonary infection. Later studies failed to confirm a significant increased risk for bacterial sepsis and meningitis among male infants [12,283–285].

## Geographic Factors

The cause of neonatal sepsis varies from hospital to hospital and from one community to another. These differences probably reflect characteristics of the population served, including unique cultural features and sexual practices, local obstetric and nursery practices, and patterns of antimicrobial agent usage. The bacteriology of neonatal sepsis and meningitis in western Europe* and Jamaica [288] is generally similar to that in the United States.

*References 10, 13, 25, 257–259, 265, 286, 287.

In tropical areas, a different pattern can be observed [289–291]. In Riyadh, Saudi Arabia, from 1980-1984, *E. coli*, *Klebsiella* species, and *Serratia* species were the dominant causes of neonatal sepsis; GBS was an infrequent cause [291]. Later data from this geographic location revealed *E. coli* and CoNS were the most common pathogens, however, causing early-onset and late-onset sepsis [292].

Every year, 4 million neonatal deaths occur. About one third of the deaths are due to sepsis [293,294]. The highest numbers of neonatal deaths are in South Central Asian countries and sub-Saharan Africa. The global perspective of neonatal sepsis is discussed in Chapter 2. The most common isolates responsible for neonatal sepsis vary by country, but include a wide spectrum of gram-negative and gram-positive species, the most common of which are *E. coli*, *S. aureus*, *Pseudomonas*, and *Klebsiella* [295]. Multidrug-resistant strains are an increasing threat to intervention programs [296,297].

GBS is the most frequent cause of early-onset and late-onset sepsis in the United States, but the rates and risk factors for maternal and neonatal GBS colonization and disease vary in different communities [298–300]. Amin and colleagues [298] in the United Arab Emirates evaluated 563 pregnant women from similar socioeconomic and ethnic backgrounds and reported a GBS colonization rate of 10.1%. In Athens, Greece, maternal and neonatal colonization rates were 6.6% and 2.4% with a vertical transmission rate of 22.5% [299]. Middle-class women followed in the private practice setting were more frequently colonized with GBS than women followed in a public hospital. No association was found between colonization with GBS and maternal age, nationality, marital status, previous obstetric history, cesarean section, infant birth weight, or preterm birth.

Stoll and Schuchat [300] reviewed data on female genital colonization with GBS from 34 reports in the literature and emphasized the importance of appropriate specimen collection and inoculation into selective (antibiotic-containing) broth media in the ascertainment of accurate colonization rates. Analysis of data from studies employing adequate methods revealed regional GBS colonization rates of 12% in India and Pakistan, 19% in Asian and Pacific countries, 19% in sub-Saharan Africa, 22% in the Middle East and North Africa, and 14% in the Americas. A comparison of studies that did and did not use selective broth media revealed significantly higher GBS colonization rates in the populations where selective broth media was employed to assess colonization. Other reasons for varying rates of GBS colonization and disease may include socioeconomic factors or differences in sexual practices, hygiene, or nutrition.

### Socioeconomic Factors

The lifestyle pattern of mothers, including cultural practices, housing, nutrition, and level of income, seems to be important in determining infants at risk for infection. The most significant factors enhancing risk for neonatal sepsis are low birth weight and prematurity, and the incidence of these is inversely related to socioeconomic status. Various criteria for determining socioeconomic status have been used, but no completely satisfactory and reproducible standard is available. Maternal education, resources, and access to health care can affect the risk of neonatal sepsis. A CDC report [301] evaluating the awareness of perinatal group B streptococcal infection among women of childbearing age in the United States revealed that women with a high school education or less; women with a household income of less than $25,000; and women reporting black, Asian/Pacific Islander, or other ethnicity had lower awareness of perinatal GBS infections than other women.

### Procedures

Most infants with very low birth weight have one or more procedures that place them at risk for infection. Any disruption of the protective capability of the intact skin or mucosa can be associated with infection. In a multicenter study of NICU patients, increased risk of bacteremia was associated with parenteral nutrition, mechanical ventilation, peripherally inserted central catheters, peripheral venous catheters, and umbilical artery catheters [302].

## NURSERY OUTBREAKS OR EPIDEMICS

The nursery is a small community of highly susceptible infants where patients have contact with many adults, including parents, physicians, nurses, respiratory therapists, and diagnostic imaging technicians (see Chapter 35). Siblings may enter the nursery or mothers' hospital suites and represent an additional source of infection. In these circumstances, outbreaks or epidemics of respiratory and gastrointestinal illness, most of which is caused by nonbacterial agents, can occur. Spread of microorganisms to the infant occurs by droplets from the respiratory tracts of parents, nursery personnel, or other infants. Organisms can be transferred from infant to infant by the hands of health care workers. Individuals with open or draining lesions are especially hazardous agents of transmission.

Staphylococcal infection and disease are a concern in many nurseries in the United States (see Chapters 14 and 35). Epidemics or outbreaks associated with contamination of nursery equipment and solutions caused by *Proteus* species, *Klebsiella* species, *S. marcescens*, *Pseudomonas* species, and *Flavobacterium* also have been reported. An unusual and unexplained outbreak of early-onset group B streptococcal sepsis with an attack rate of 14 per 1000 live births occurred in Kansas City during January through August of 1990 [303].

Molecular techniques to distinguish among bacterial strains are an important epidemiologic tool in the investigation of nursery outbreaks. Previously, methods to determine strain relatedness relied on antibiotic susceptibility patterns, biochemical profiles, and plasmid or phage analysis [154,304]. More recent techniques permit the discrimination of strains based on bacterial chromosomal polymorphisms. Pulse-field gel electrophoresis, ribotyping, multilocus sequence typing, and polymerase chain reaction–based methods are widely used tools to assign strain identity or relatedness [305–307].

Antimicrobial agents play a major role in the ecology of the microbial flora in the nursery. Extensive and

prolonged use of these drugs eliminates susceptible strains and allows for proliferation of resistant subpopulations of neonatal flora. There is selective pressure toward colonization by microorganisms that are resistant to the antimicrobial agents used in the nurseries and, because of cross-resistance patterns, to similar drugs within an antimicrobial class.

A historical example of the selective pressure of a systemic antimicrobial agent is provided by Gezon and coworkers [45] in their use of benzathine penicillin G to control an outbreak of group A streptococcal disease. All infants entering the nursery during a 3-week period were treated with a single intramuscular dose of penicillin. Before institution of this policy, most strains of *S. aureus* in the nursery were susceptible to penicillin G. One week after initiation of the prophylactic regimen and for the next 2 years, almost all strains of *S. aureus* isolated from newborns in this nursery were resistant to penicillin G.

During a 4-month period in 1997, van der Zwet and colleagues [308] investigated a nosocomial nursery outbreak of gentamicin-resistant *K. pneumoniae* in which 13 neonates became colonized and 3 became infected. Molecular typing of strains revealed clonal similarity of isolates from eight neonates. The nursery outbreak was terminated by the substitution of amikacin for gentamicin in neonates when treatment with an aminoglycoside was believed to be warranted. Development of resistance in gram-negative enteric bacilli also has been documented in an Israeli study after widespread use of aminoglycosides [309].

Extensive or routine use of third-generation cephalosporins in the nursery, especially for all neonates with suspected sepsis, can lead to more rapid emergence of drug-resistant gram-negative enteric bacilli than occurs with the standard regimen of ampicillin and an aminoglycoside. Investigators in Brazil [126] performed a prospective investigation of extended-spectrum β-lactamase–producing *K. pneumoniae* colonization and infection during the 2-year period 1997-1999 in the NICU. A significant independent risk factor for colonization was receipt of a cephalosporin and an aminoglycoside. Previous colonization was an independent risk factor for infection. In India, Jain and coworkers [137] concluded that indiscriminate use of third-generation cephalosporins was responsible for the selection of extended-spectrum β-lactamase–producing, multiresistant strains in their NICU, where extended-spectrum β-lactamase production was detected in 86.6% of *Klebsiella* species, 73.4% of *Enterobacter* species, and 63.6% of *E. coli* strains. Nosocomial infections in the nursery and their epidemiology and management are discussed further in Chapter 35.

## PATHOGENESIS

The developing fetus is relatively protected from the microbial flora of the mother. Procedures disturbing the integrity of the uterine contents, such as amniocentesis [310], cervical cerclage [311,312], transcervical chorionic villus sampling [313], or percutaneous umbilical blood sampling [310,314], can permit entry of skin or vaginal organisms into the amniotic sac, however, causing amnionitis and secondary fetal infection.

Initial colonization of the neonate usually occurs after rupture of the maternal membranes [280,315]. In most cases, the infant is colonized with the microflora of the birth canal during delivery. If delivery is delayed, vaginal bacteria may ascend the birth canal and, in some cases, produce inflammation of the fetal membranes, umbilical cord, and placenta [316]. Fetal infection can result from aspiration of infected amniotic fluid [317], leading to stillbirth, premature delivery, or neonatal sepsis [310,316, 318,319]. The organisms most commonly isolated from infected amniotic fluid are GBS, *E. coli* and other enteric bacilli, anaerobic bacteria, and genital mycoplasmas [310,318].

Studies have reported that amniotic fluid inhibits the growth of *E. coli* and other bacteria because of the presence of lysozyme, transferrin, immunoglobulins (IgA and IgG, but not IgM), zinc and phosphate, and lipid-rich substances [319–325]. The addition of meconium to amniotic fluid in vitro has resulted in increased growth of *E. coli* and GBS in some studies [326,327]. In other in vitro studies of the bacteriostatic activity of amniotic fluid, the growth of GBS was not inhibited [328–330]. Bacterial inhibition by amniotic fluid is discussed further in Chapter 3.

Infection of the mother at the time of birth, particularly genital infection, can play a significant role in the development of infection in the neonate. Transplacental hematogenous infection during or shortly before delivery (including the period of separation of the placenta) is possible, although it is more likely that the infant is infected just before or during passage through the birth canal. Among reports of concurrent bacteremia in the mother and neonate are cases caused by *H. influenzae* type b [331], *H. parainfluenzae* [208], *S. pneumoniae* [58,332], group A streptococcus [42], *N. meningitidis* [182], *Citrobacter* species [333], and *Morganella morgagnii* [334]; concurrent cases of meningitis have been reported as caused by *S. pneumoniae* [335], *N. meningitidis* [182], and GBS [336]. Many neonates are bacteremic at the time of delivery, which indicates that invasive infection occurred antepartum [337]. Infants with signs of sepsis during the first 24 hours of life also have the highest mortality rate [10]. These data suggest the importance of initiating chemoprophylaxis for women with group B streptococcal colonization or other risk factors for invasive disease in the neonate at the time of onset of labor (see Chapter 12) [338].

Microorganisms acquired by the newborn just before or during birth colonize the skin and mucosal surfaces, including the conjunctivae, nasopharynx, oropharynx, gastrointestinal tract, umbilical cord, and, in the female infant, the external genitalia. Normal skin flora of the newborn includes CoNS, diphtheroids, and *E. coli* [339]. In most cases, the microorganisms proliferate at the initial site of attachment without resulting in illness. Occasionally, contiguous areas may be infected by direct extension (e.g., sinusitis and otitis can occasionally occur from upper respiratory tract colonization).

Bacteria can be inoculated into the skin and soft tissue by obstetric forceps, and organisms may infect these tissues if abrasions or congenital defects are present. Scalp abscesses can occur in infants who have electrodes placed

during labor for monitoring of heart rate [85,340,341]. The incidence of this type of infection in the hands of experienced clinicians is generally quite low (0.1% to 5.2%), however [342]. A 10-year survey of neonatal enterococcal bacteremia detected 6 of 44 infants with scalp abscesses as the probable source of their bacteremia [85]. The investigators were unable to deduce from the data available whether these abscesses were associated with fetal scalp monitoring, intravenous infusion, or other procedures that resulted in loss of the skin barrier.

Transient bacteremia can accompany procedures that traumatize mucosal membranes such as endotracheal suctioning [343]. Invasion of the bloodstream also can follow multiplication of organisms in the upper respiratory tract or other foci. Although the source of bacteremia frequently is inapparent, careful inspection can reveal a focus, such as an infected circumcision site or infection of the umbilical stump, in some neonates. Metastatic foci of infection can follow bacteremia and can involve the lungs, kidney, spleen, bones, or CNS.

Most cases of neonatal meningitis result from bacteremia. Fetal meningitis followed by stillbirth [344] or hydrocephalus, presumably because of maternal bacteremia and transplacentally acquired infection, has been described, but is exceedingly rare. Although CSF leaks caused by spiral fetal scalp electrodes do occur, no cases of meningitis have been traced to this source [345,346]. After delivery, the meninges can be invaded directly from an infected skin lesion, with spread through the soft tissues and skull sutures and along thrombosed bridging veins [315], but in most circumstances, bacteria gain access to the brain through the bloodstream to the choroid plexus during the course of sepsis [344]. Infants with developmental defects, such as a midline dermal sinus or myelomeningocele, are particularly susceptible to invasion of underlying nervous tissue [23].

Brain abscesses can result from hematogenous spread of microorganisms (i.e., septic emboli) and proliferation in tissue that is devitalized because of anoxia or vasculitis with hemorrhage or infarction. Certain organisms are more likely than others to invade nervous tissue and cause local or widespread necrosis [23]. Most cases of meningitis related to *C. koseri* (formerly *C. diversus*) and *E. sakazakii* are associated with formation of cysts and abscesses. Other gram-negative bacilli with potential to cause brain abscesses include *Proteus*, *Citrobacter*, *Pseudomonas*, *S. marcescens*, and occasionally GBS [155,166,347–349]. Volpe [350] commented that bacteria associated with brain abscesses are those that cause meningitis with severe vasculitis.

## HOST FACTORS PREDISPOSING TO NEONATAL BACTERIAL SEPSIS

Infants with one or more predisposing factors (e.g., low birth weight, premature rupture of membranes, septic or traumatic delivery, fetal hypoxia, maternal peripartum infection) are at increased risk for sepsis. Microbial factors such as inoculum size [351] and virulence properties of the organism [310] undoubtedly are significant. Immature function of phagocytes and decreased inflammatory and immune effector responses are characteristic of very small infants and can contribute to the unique susceptibility of the fetus and newborn (see Chapter 4).

Metabolic factors are likely to be important in increasing risk for sepsis and severity of the disease. Fetal hypoxia and acidosis can impede certain host defense mechanisms or allow localization of organisms in necrotic tissues. Infants with hyperbilirubinemia can have impairment of various immune functions, including neutrophil bactericidal activity, antibody response, lymphocyte proliferation, and complement functions (see Chapter 4). Indirect hyperbilirubinemia that commonly occurs with breast-feeding jaundice rarely is associated with neonatal sepsis [352]. Late-onset jaundice and direct hyperbilirubinemia can be the result of an infectious process. In one study from Turkey, more than one third of infants with late-onset direct hyperbilirubinemia had culture-proven sepsis, with gram-negative enteric bacteria including *E. coli* the most common etiologic agent [353]. Evidence of diffuse hepatocellular damage and bile stasis has been described in such infected and jaundiced infants [354,355].

Hypothermia in newborns, generally defined as a rectal temperature equal to or less than 35° C (≤95° F), is associated with a significant increase in the incidence of sepsis, meningitis, pneumonia, and other serious bacterial infections [356–359]. In developing countries, hypothermia is a leading cause of death during the winter. Hypothermia frequently is accompanied by abnormal leukocyte counts, acidosis, and uremia, each of which can interfere with resistance to infection. The exact cause of increased morbidity in infants presenting with hypothermia is poorly understood, however. In many infants, it is unclear whether hypothermia predisposes to or results from bacterial infection. In a large outbreak of *S. marcescens* neonatal infections affecting 159 cases in Gaza City, Palestine, hypothermia was the most common presenting symptom, recorded in 38% of cases [360].

Infants with galactosemia have increased susceptibility to sepsis caused by gram-negative enteric bacilli, in particular *E. coli* [361–363]. Among eight infants identified with galactosemia by routine newborn screening in Massachusetts, four had systemic infection caused by *E. coli* [362]. Three of these four infants died of sepsis and meningitis; the fourth infant, who had a urinary tract infection, survived. A survey of state programs in which newborns are screened for galactosemia revealed that among 32 infants detected, 10 had systemic infection, and 9 died of bacteremia. *E. coli* was the infecting organism in nine of the infants. Galactosemic neonates seem to have an unusual predisposition to severe infection with *E. coli*, and bacterial sepsis is a significant cause of death among these infants. Depressed neutrophil function resulting from elevated serum galactose levels is postulated to be a possible cause of their predisposition to sepsis [364,365]. The gold standard for diagnosis of classic galactosemia is measurement of galactose-1-phosphate uridyltransferase activity in erythrocytes, and the sole therapy is galactose restriction in the diet [366]. Shurin [364] observed that infants became ill when serum galactose levels were high when glucose levels were likely to be low, and that susceptibility to infection diminished when dietary control was initiated.

Other inherited metabolic diseases have not been associated with a higher incidence of neonatal bacterial infection. A poorly documented increase in the relative frequency of sepsis has been observed in infants with hereditary fructose intolerance [367]. Infants with methylmalonic acidemia and other inborn errors of branched-chain amino acid metabolism manifest neutropenia as a result of bone marrow suppression by accumulated metabolites; however, no increased incidence of infection has been described in this group of infants [368,369].

Iron may have an important role in the susceptibility of neonates to infection, but this is controversial. Iron added to serum in vitro enhances the growth of many organisms, including *E. coli*, *Klebsiella* species, *Pseudomonas* species, *Salmonella* species, *L. monocytogenes*, and *S. aureus*. The siderophore Iron is a proven virulence factor for the bacteremic phase of *E. coli* K1 sepsis and meningitis in the neonatal rat infection model [370]. The iron-binding proteins lactoferrin and transferrin are present in serum, saliva, and breast milk. The newborn has low levels of these proteins, however [371]. The iron-sequestering capacity of oral bovine lactoferrin supplementation may be one contributing factor to its reported efficacy in prophylaxis of bacterial sepsis in very low birth weight infants [372].

Barry and Reeve [373] showed an increased incidence of sepsis in Polynesian infants who were treated with intramuscular iron as prophylaxis for iron deficiency anemia. The regimen was shown to be effective in preventing anemia of infancy, but an extraordinary increase in bacterial sepsis occurred. The incidence of sepsis in newborns receiving iron was 17 cases per 1000 live births, whereas the incidence of sepsis in infants who did not receive iron was 3 cases per 1000 live births; during a comparable period, the rate of sepsis for European infants was 0.6 case per 1000 live births. Special features of sepsis in the infants who received iron soon after birth were late onset, paucity of adverse perinatal factors, and predominance of *E. coli* as the cause of sepsis. During the period studied, *E. coli* was responsible for 26 of 27 cases of sepsis in iron-treated Polynesian infants and for none of three cases of sepsis in the infants who did not receive iron. Results of this study were similar to the experience reported by Farmer [374] for New Zealand infants given intramuscular iron. The incidence of meningitis caused by *E. coli* increased fivefold in infants who received iron and decreased when the use of iron was terminated. Conventional iron-supplemented human milk fortifiers seem to be safe and do not contribute to a higher rate of sepsis in preterm infants [375].

## INFECTION IN TWINS

Studies have suggested a higher risk for contracting ascending intrauterine infection in the first than the second born of twins [376,377]. Comparing delivery methods, no difference was observed in the incidence of neonatal sepsis in twins delivered in the vertex/vertex position compared with cases requiring uterine manipulation (vertex/breech extraction) [378]. Vaginal delivery of twin A followed by cesarean delivery of twin B may be associated with a higher rate of endometritis and neonatal sepsis, however, compared with cases in which both twins are delivered by cesarean section [379].

Pass and colleagues [380] showed that low birth weight twins were at higher risk for group B streptococcal infection than low birth weight singletons; infection developed in 3 of 56 twin births, or 53.5 cases per 1000 live births, compared with infections in 7 of 603 singleton births, or 11.6 cases per 1000 live births. Edwards and associates [381] studied group B streptococcal infection in 12 index cases of multiple gestations. Early-onset disease occurred in both twins in one pair and in one twin in five other pairs; late-onset infection occurred in both twins in two pairs and in one twin in four other pairs. Cases of late-onset group B streptococcal disease in twin pairs occurred closely in time to one another: 19 and 20 days of age in one set and 28 and 32 days of age in the other set. In another case report of late-onset group B streptococcal infection in identical twins, twin A had fulminant fatal meningitis, whereas twin B recovered completely. GBS isolates proved to be genetically identical; clinical variables associated with the adverse outcome in twin A were longer duration of fever before antibiotics and the development of neutropenia [382].

In twins, the presence of virulent organisms in the environment, especially the maternal genital tract; the absence of specific maternal antibodies; and their similar genetic heritage probably contribute to the risk for invasive infection. It seems logical that twins, particularly if monochorionic, should have high rates of simultaneous early-onset infection, but it is particularly intriguing that some cases of late-onset disease occur in twins almost simultaneously. Late onset sepsis in a twin warrants close observation and consideration of cultures and presumptive therapy in the asymptomatic twin [383, 384a].

Infections in twins, including disease related to *Treponema pallidum*, echoviruses 18 and 19, and *Toxoplasma gondii*, are discussed in Chapters 16, 24, and 31. Neonatal infections in twins have been caused by group A streptococci (case report of streptococcal sepsis in a mother and infant twins) [384], *Salmonella* species [385], *Salmonella E. coli* [384a], *C. koseri* (brain abscesses in twins) [156], malaria [386,387], coccidioidomycosis [388], cytomegalovirus infection [389–391], and rubella [392].

## UMBILICAL CORD AS A FOCUS OF INFECTION

Historically, the umbilical cord was a particularly common portal of entry for systemic infection in newborns, and infection by this route can still occur. The devitalized tissue is an excellent medium for bacterial growth, the recently thrombosed umbilical vessels provide access to the bloodstream, the umbilical vein is a direct route to the liver, and the umbilical artery and urachus are pathways to the pelvis [393]. Epidemics of erysipelas, staphylococcal disease, tetanus, and gas gangrene of the umbilicus were common in the 19th century. The introduction of simple hygienic measures in cord care resulted in a marked reduction of omphalitis [394]. In 1930, Cruickshank [395] wrote, "in Prague, before antiseptic and aseptic dressing of the cord was introduced, sepsis neonatorum was as common as puerperal sepsis … after the introduction of cord dressing in the hospital the

number of newborn children developing fever sank from 45% to 11.3%." [396]

Closure of the umbilical vessels and the subsequent aseptic necrosis of the cord begins soon after the infant takes the first breath. The umbilical arteries contract; the blood flow is interrupted; and the cord tissues, deprived of a blood supply, undergo aseptic necrosis. The umbilical stump acquires a rich flora of microorganisms. Within hours, the umbilical stump is colonized with large numbers of gram-positive cocci, particularly *Staphylococcus* species, and shortly thereafter with fecal organisms [396,397]. These bacteria can invade the open umbilical wound, causing a localized infection with purulent discharge and, as a result of delayed obliteration of the umbilical vessels, bleeding from the umbilical stump. From this site, infection can proceed into the umbilical vessels, along the fascial planes of the abdominal wall, or into the peritoneum (Fig. 6–1) [396,398,399].

Although umbilical discharge or an "oozing" cord is the most common manifestation of omphalitis, periumbilical cellulitis and fasciitis are the conditions most often associated with hospitalization [398]. Infants presenting with fasciitis have a high incidence of bacteremia, intravascular coagulopathy, shock, and death [398]. Edema of the umbilicus and peau d'orange appearance of the surrounding abdominal skin, signaling obstruction of the underlying lymphatics, can be an early warning sign, whereas the pathognomonic purplish blue discoloration implies advanced necrotizing fasciitis [393]. Septic embolization arising from the infected umbilical vessels is

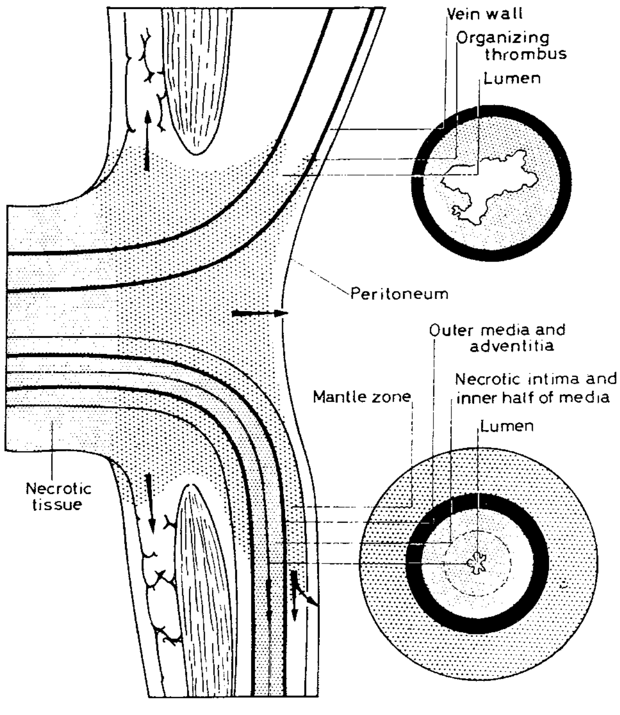

**FIGURE 6–1** After birth, the necrotic tissue of the umbilical stump separates. This provokes some inflammation, which is limited by a fibroblastic reaction extending to the inner margin of the *coarsely stippled area*. The inner half of the media and the intima of the umbilical arteries become necrotic, but this does not stimulate an inflammatory reaction. *Arrows* indicate routes by which infection may spread beyond the granulation tissue barriers. Organisms invading the thrombus in the vein may disseminate by emboli. *(From Morison JE. Foetal and Neonatal Pathology, 3rd ed. Washington, DC, Butterworth, 1970.)*

uncommon, but can produce metastatic spread to various organs, including the lungs, pancreas, kidneys, and skin [394]. Such emboli can arise from the umbilical arteries and from the umbilical vein, because final closure of the ductus venosus and separation of the portal circulation from the inferior vena cava and the systemic circulation are generally delayed until day 15 to 30 of life [400].

Although omphalitis is now a rare infection in developing countries, it is a significant cause of mortality in developing countries. Topical application of chlorhexidine to the umbilical chord was shown to decrease the incidence of omphalitis in neonates in southern Nepal [400a]. Complications of omphalitis include various infections, such as septic umbilical arteritis [394,401], suppurative thrombophlebitis of the umbilical or portal veins or the ductus venosus [401–403], peritonitis [399,401,402,404], intestinal gangrene [399], pyourachus (infection of the urachal remnant) [405], liver abscess, endocarditis, pyelophlebitis [399,406], and subacute necrotizing funisitis [407]. Some of these infections can occur in the absence of signs of omphalitis [394,401].

## ADMINISTRATION OF DRUGS TO THE MOTHER BEFORE DELIVERY

Almost all antimicrobial agents cross the placenta. Antimicrobial drugs administered to the mother at term can alter the initial microflora of the neonate and can complicate the diagnosis of infection in the neonate. Chapter 37 reviews the clinical pharmacology of antimicrobial agents administered to the mother.

Studies have shown that corticosteroid administration to mothers in preterm labor to enhance pulmonary maturation in the fetus resulted in a significant decrease in the incidence and severity of neonatal respiratory distress syndrome, but an increase in maternal infection, particularly endometritis, compared with placebo [408]; however, the impacts of this practice on the risk of neonatal infection differed among early studies [408,409]. Roberts and Dalziel [410] more recently performed a large meta-analysis of 21 randomized controlled studies from the Cochrane Pregnancy and Childbirth Group Trials register, comprising 3885 pregnant women and 4269 infants, and concluded that antenatal corticosteroid administration (betamethasone, dexamethasone, or hydrocortisone) given to women expected to deliver singleton or multiple pregnancies, whether labor was spontaneous, induced by membrane rupture, or electively induced, was associated with multiple favorable outcomes, including reduced neonatal death (relative risk 0.69), intensive care admissions (relative risk 0.80) and systemic infections in the first 48 hours of life (relative risk 0.56).

Substance abuse during pregnancy can affect immune function in the neonate. Significant abnormalities in T-cell function and an apparent increased incidence of infections have been found during the first year of life among infants born to alcohol-addicted [411–413] and heroin-addicted [414,415] mothers. The adverse effects of cocaine and opiates on placental function, fetal growth and development, and prematurity also may predispose to a greater likelihood of neonatal infection [415,416]. Drug abuse is a multifactorial problem; it is virtually impossible to separate the consequences of direct pharmacologic effects on the fetus from the consequences secondary to

inadequate nutrition, lack of prenatal care, and infectious medical complications encountered in addicted pregnant women [415,416].

## ADMINISTRATION OF DRUGS OTHER THAN ANTIBIOTICS TO THE NEONATE

Administration of indomethacin to neonates for the closure of a patent ductus arteriosus has been associated with a higher incidence of sepsis and necrotizing enterocolitis in the indomethacin-treated groups compared with infants treated with surgery or other medications [417–419]. The mechanism by which indomethacin predisposes low birth weight infants to sepsis is unknown [420]. A meta-analysis of studies comparing ibuprofen with indomethacin for patent ductus arteriosus closure did not identify differences in the incidence of sepsis, mortality, or duration of hospitalization [421].

O'Shea and colleagues [420] described the outcomes of very low birth weight (500 to 1250 g) infants given dexamethasone at 15 to 25 days of age for the prevention of chronic lung disease. Among 61 infants treated with tapering doses of dexamethasone for 42 days, there was no increase in the incidence of sepsis or the number of sepsis evaluations in the treatment group compared with a control population. Further trials of dexamethasone administration for prophylaxis of chronic lung disease in very low birth weight infants confirmed a lack of increased risk for sepsis [422].

A strong association between intravenous lipid administration to newborns and bacteremia caused by CoNS has been established [99,423]. The role of lipid as a nutritional source for the bacteria, mechanical blockage of the catheter by deposition of lipid in the lumen, and the effect of lipid emulsions on the function of neutrophils and macrophages each might contribute to the observed increased risk for bacteremia. Avila-Figueroa and colleagues [423] identified exposure to intravenous lipids at anytime during hospitalization as the most important risk factor (odds ratio 9.4) for development of CoNS bacteremia in very low birth weight infants, calculating that 85% of these bacteremias were attributable to lipid therapy. A randomized trial found that changing intravenous tubing for lipid infusion in neonates every 24 hours instead of every 72 hours may reduce bloodstream infections and mortality by approximately 50% [424].

More recently, a surprisingly strong association between ranitidine therapy in neonates admitted to one NICU and the risk of late-onset bacterial sepsis was reported [425]. The mechanism for such an association is unclear, but warrants further analysis.

## PATHOLOGY

Infants with severe and rapidly fatal sepsis generally have minimal or no histologic indication of an infectious process [315,426]. Findings typical of bacteremia, such as multiple disseminated abscesses of similar size, purulent vasculitis, and intravascular identification of bacteria, are evident in a few infants [426]. Shock accompanying sepsis sometimes causes findings such as periventricular leukomalacia and intraventricular hemorrhage, scattered areas of nonzonal hepatic necrosis, renal medullary hemorrhage, renal cortical or acute tubular necrosis, and adrenal hemorrhage and necrosis. Evidence of disseminated intravascular coagulopathy, manifested by strands of interlacing fibrin in the vessels or by a well-demarcated subarachnoid fibrinous hematoma, also can be present [344,426]. The pathology of infections of the respiratory, genitourinary, and gastrointestinal tracts and focal suppurative diseases is discussed in subsequent chapters.

The pathology of neonatal meningitis [344,427,428] and brain abscess [429,430] is similar to that in older children and adults. The major features are ventriculitis (including inflammation of the choroid plexus), vasculitis, cerebral edema, infarction, cortical neuronal necrosis, and periventricular leukomalacia; chronic pathologic features include hydrocephalus, multicystic encephalomalacia and porencephaly, and cerebral cortical and white matter atrophy [431]. Significant collections of purulent material can be present in the sulci and subarachnoid space, particularly around the basal cisterns, of infants with meningitis. Because the fontanelles are open, exudative material can collect around the base of the brain without a significant increase in intracranial pressure. Hydrocephalus may result from closure of the aqueduct or the foramina of the fourth ventricle by purulent exudate or by means of inflammatory impairment of CSF resorption through the arachnoid channels [344,432]. Ventriculitis has been described in 20% to 90% of cases [23,344,432] and often is the reason for persistence of bacteria in CSF when obstruction ensues and for a slow clinical recovery [433]. Acute inflammatory cells infiltrate the ependymal and subependymal tissues, causing destruction of the epithelial lining of the ventricles. Hemorrhage, venous thrombosis, and subdural effusions often are present.

Brain abscesses and cysts in the neonate are distinguished by the large size of the lesions and poor capsule formation. They occur most frequently in association with meningitis caused by *C. koseri*, *E. sakazakii*, *S. marcescens*, and *Proteus mirabilis* and usually are located in the cerebrum, involving several lobes [155,166,347,429]. These organisms characteristically give rise to a hemorrhagic meningoencephalitis caused by intense bacterial infiltration of cerebral vessels and surrounding tissues. The resulting vascular occlusion is followed by infarction and widespread necrosis of cerebral tissue with liquefaction and formation of multiple loculated abscesses and cysts [347,350].

## CLINICAL MANIFESTATIONS

Signs of fetal distress can be the earliest indication of infection in neonates with sepsis, beginning at or soon after delivery. Fetal tachycardia in the second stage of labor was evaluated as a sign of infection by Schiano and colleagues [434]. Pneumonia or sepsis occurred in 3 of 8 infants with marked fetal tachycardia (>180 beats/min), in 7 of 32 infants with mild tachycardia (160 to 179 beats/min), and in 1 of 167 infants with lower heart rates. Maternal risk factors such as premature rupture of membranes, foul-smelling amniotic fluid, and evidence of acute placental inflammation are associated with increased risk of neonatal sepsis and should prompt detailed evaluation of the newborn [435,436].

A low Apgar score, suggesting distress at or before delivery, also has been correlated with sepsis and

associated adverse outcomes in the newborn period [435,437]. Infants delivered vaginally had a 56-fold higher risk of sepsis when the Apgar score was less than 7 at 5 minutes compared with infants with higher Apgar scores [438]. Among infants born after rupture of the amniotic membranes for 24 hours or more, St. Geme and colleagues [316] found a significant increase in the risk for perinatal bacterial infection in infants with an Apgar score of less than 6 at 5 minutes, but found no association with fetal tachycardia (>160 beats/min).

The Apgar score is well characterized in term infants, but less so in premature infants, who have higher attack rates for sepsis. Because low Apgar scores (<3 at 1 minute, <6 at 5 minutes) were significantly associated with low birth weight and shorter gestation, the use of the score is less valuable as an indicator of sepsis in premature than in term infants [439].

The earliest signs of sepsis often are subtle and nonspecific. Poor feeding, diminished activity, or "not looking well" can be the only early evidence that infection is present. More prominent findings are respiratory distress; apnea; lethargy; fever or hypothermia; jaundice; vomiting; diarrhea; and skin manifestations, including petechiae, abscesses, and sclerema [440]. The nonspecific and subtle nature of the signs of sepsis in newborns is even more problematic in identifying sepsis in infants with very low birth weight. In a study by Fanaroff and colleagues [18], the clinical signs of late-onset sepsis in 325 infants weighing 501 to 1500 g at birth included increasing apnea and bradycardia episodes (55%), increasing oxygen requirement (48%), feeding intolerance, abdominal distention or guaiac-positive stools (46%), lethargy and hypotonia (37%), and temperature instability (10%). Unexplained metabolic acidosis (11%) and hypoglycemia (10%) were the most common laboratory indicators of the metabolic derangement accompanying sepsis.

Bonadio and coworkers [441] attempted to determine the most reliable clinical signs of sepsis in more than 200 febrile infants from birth to 8 weeks old. They found that changes in affect, peripheral perfusion, and respiratory status best identified infants with serious bacterial infection. Alterations in feeding pattern, level of alertness, level of activity, and muscle tone also were present; however, these signs were less sensitive indicators. More recently, Kudawla and associates [442] developed a scoring system for late-onset neonatal sepsis in infants weighing 1000 to 2500 g. Clinical parameters included lethargy, tachycardia, grunting, abdominal distention, increased prefeed residual gastric aspirates, fever, and chest retractions. These data needed to be combined with laboratory parameters such as elevated C-reactive protein or absolute neutrophil or band count to achieve high sensitivity and specificity.

Focal infection involving any organ can occur in infants with sepsis, but most often (excluding pneumonia or meningitis), this occurs in neonates with late-onset rather than early-onset disease. Evaluation of infants with suspected bacteremia must include a careful search for primary or secondary foci, such as meningitis, pneumonia, urinary tract infection, septic arthritis, osteomyelitis, peritonitis, or soft tissue infection.

Serious bacterial infections are uncommon in neonates without any clinical evidence of illness [441], even among infants with maternal risk factors for infection [443]. Occasionally, bacteremia occurs without clinical signs [444–446]. Albers and associates [444] described case histories of three infants without signs of illness for whom blood cultures were performed as part of a nursery study involving 131 infants. Blood was obtained from peripheral veins at different times during the first 10 days of life. The same pathogen was isolated repeatedly (i.e., three, three, and two times) from the blood of the three infants even though they remained well. The infants subsequently were treated with appropriate antimicrobial agents. Bacteremia caused by GBS can occur with minimal or no systemic or focal signs [446–448], and it may be sustained over several days [449]. Most healthy-appearing infants with group B streptococcal bacteremia were born at term and had early-onset (<7 days old) infection. Similarly, among 44 neonates with enterococcal bacteremia, 3 of 18 with early-onset infection but none with late-onset infection appeared well [85]. The true incidence of bacteremia without clinical signs is uncertain because few cultures of blood are performed for infants who show no signs of sepsis.

Table 6–13 lists the common clinical signs of neonatal bacterial sepsis. Clinical signs of neonatal bacterial meningitis are presented in Table 6–14. Noninfectious conditions with clinical manifestations similar to those of sepsis are listed in Table 6–15.

**TABLE 6–13** Clinical Signs of Bacterial Sepsis

| Clinical Sign | Percent of Infants with Sign |
|---|---|
| Hyperthermia | 51 |
| Hypothermia | 15 |
| Respiratory distress | 33 |
| Apnea | 22 |

## FEVER AND HYPOTHERMIA

The temperature of an infant with sepsis may be elevated, depressed, or normal [447–453]. In a multicenter survey of nearly 250 infants with early-onset group B streptococcal bacteremia, approximately 85% had a normal temperature (36° C to 37.2° C [96.8° F to 99° F]) at the time of their admission to the NICU [447]. Comparing temperatures by gestational age, it was observed that term infants were more likely to have fever than preterm infants (12% versus 1%), whereas preterm infants more frequently had hypothermia (13% versus 3%). Phagocytes of an infant born after an uncomplicated labor can produce adult concentrations of interleukin-1, a potent pyrogen. The phagocytes of infants born after cesarean section have a markedly suppressed ability to produce this pyrogen [454]. In the studies reviewed in Table 6–13, approximately half of the infants had fever. Hypothermia, which was mentioned in one study, occurred in 15% of the infants.

Fever is variably defined for newborns. A temperature of 38° C (100.4° F) measured rectally generally is accepted

as the lower limit of the definition of fever. Although some clinical studies indicate that axillary [455], skin-mattress [456], and infrared tympanic membrane thermometry [457] are accurate and less dangerous than rectal measurements for obtaining core temperature, the reliability of these methods, particularly in febrile infants, has been questioned [458–460]. A study established that statistically significant differences are present between the rectal and axillary temperatures obtained in newborns during the first 4 days of life even with the same electronic temperature device [461]. The current method of choice for determining the presence of fever in neonates is a rectal temperature taken at a depth of 2 to 3 cm past the anal margin. In infants with suspected sepsis without fever, it has been shown that a difference between core (rectal) and skin (sole of the foot) temperature of more than 3.5° C can be a more useful indicator of infection than measurement of core temperature alone [453].

There is no study of temperatures in neonates that is prospective, assesses all infants (febrile and afebrile), includes rectal and axillary temperatures, includes preterm and term infants, and requires positive cultures of blood or other body fluids to define invasive bacterial infection. Voora and colleagues [462] observed 100 term infants in Chicago with an axillary or rectal temperature of equal to or greater than 37.8° C (≥100.1° F) during the first 4 days of life, and Osborn and Bolus [463] conducted a retrospective review of 2656 term infants in Los Angeles. Both groups of investigators reported that temperature elevation in healthy term infants was uncommon. Approximately 1% of neonates born at term had at least one episode of fever, measured as equal to or greater than 37.8° C (≥100.1° F) per axilla [462]. Temperature elevation infrequently was associated with systemic infection when a single evaluation occurred. None of 64 infants in these two studies who had a single episode of fever developed clinical evidence of systemic infection (cultures of blood or other body fluids were not obtained). By contrast, temperature elevation that was sustained for more than 1 hour frequently was associated with infection. Of seven infants with sustained fever in the study by Osborn and Bolus [463], five had proven bacterial or viral infections. Of 65 infants reported by Voora and colleagues [462], 10 had documented systemic bacterial disease. Temperature elevation without other signs of infection was infrequent. Only one infant (with cytomegalovirus infection) of the five Los Angeles infants had fever without other signs. Only 2 infants (with bacteremia caused by *E. coli* or GBS) of the 10 Chicago infants with fever and proven bacterial disease had no other signs of infection.

In addition to infection, fever may be caused by an elevation in ambient temperature, dehydration, retained blood or extensive hematoma, and damage to the temperature-regulating mechanisms of the CNS. Less common noninfectious causes of fever are hyperthyroidism, cystic fibrosis, familial dysautonomia, and ectodermal dysplasia. When thermoregulatory devices that monitor and modify infant temperature are introduced, the use of fever or hypothermia as a diagnostic sign of sepsis sometimes is impeded.

## RESPIRATORY DISTRESS

Signs of respiratory distress, including tachypnea, grunting, flaring of the alae nasi, intercostal retractions, rales, and decreased breath sounds, are common and important findings in the infant suspected to have sepsis. Respiratory distress syndrome and aspiration pneumonia must be considered in the differential diagnosis. Apnea is one of the most specific signs of sepsis, but usually occurs in the setting of a fulminant onset or after other nonspecific signs have been present for hours or days. Clinical signs of cardiovascular dysfunction, including tachycardia, arrhythmia, and poor peripheral perfusion, that occur in the absence of congenital heart disease are sensitive and specific signs of sepsis.

## JAUNDICE

Jaundice is present in approximately one third of infants with sepsis and is a common finding in infants with urinary tract infection [353,464–468]. It can develop suddenly or subacutely and occasionally is the only sign of sepsis. Jaundice usually decreases after institution of appropriate antimicrobial therapy. It occurs in septic infants regardless of the type of bacterial pathogen.

## ORGANOMEGALY

The liver edge is palpable in premature infants and can extend to 2 cm below the costal margin in healthy term infants. Ashkenazi and colleagues [469] evaluated liver size in healthy term infants examined within 24 hours of birth and again at 72 to 96 hours. Measurements ranged from 1.6 to 4 cm below the costal margin, and there was no significant difference between early and late examinations. Reiff and Osborn [470] suggested that determination of liver span by palpation and percussion is a more reliable technique than identifying the liver projection below the costal margin. Hepatomegaly is a common sign of in utero infections and of some noninfectious conditions, such as cardiac failure and metabolic diseases, including galactosemia and glycogen storage disease. Tender hepatomegaly can be a sign of bacterial liver abscess in neonates, a potential complication of misplaced central umbilical catheters [125]. Splenomegaly is less common than hepatomegaly and infrequently is mentioned in reports of bacterial sepsis of the newborn [471].

Lymph nodes infrequently are palpable in newborns unless they are infected with viruses, spirochetes, or protozoa. Bamji and coworkers [472] examined 214 healthy neonates in New York and identified palpable nodes at one or more sites in one third of the infants. Embree and Muriithi [473] examined 66 healthy term Kenyan neonates during the first 24 hours of life and found palpable axillary nodes (27.7%), but no palpable inguinal nodes. Adenopathy is a sign of congenital infection caused by rubella virus, *T. gondii*, *T. pallidum*, and enteroviruses. Adenitis can occur in drainage areas involved with bacterial soft tissue infection. Although adenopathy is not an important sign of systemic bacterial infection in neonates, cellulitis-adenitis syndrome, a rare clinical manifestation of late-onset group B streptococcal infection in infants,

is a condition in which local inflammation can be the only initial sign of sepsis that can include concurrent meningitis [474–476].

## GASTROINTESTINAL SIGNS

Gastrointestinal disturbances, including poor feeding, regurgitation or vomiting, large gastric residuals in infants fed by tube, diarrhea, and abdominal distention, are common and significant early signs of sepsis. The first indications of illness can be a change in feeding pattern or lethargy during feedings.

## SKIN LESIONS

Various skin lesions can accompany bacteremia, including cellulitis, abscess, petechiae, purpuric lesions, sclerema, erythema multiforme, and ecthyma. These lesions are described in Chapter 10.

## NEUROLOGIC SIGNS

The onset of meningitis in the neonate is accompanied by identical signs of illness as observed in infants with sepsis. Meningitis can be heralded by increasing irritability, alteration in consciousness, poor tone, tremors, lip smacking, or twitching of facial muscles or an extremity. Seizures were present in 31% of the infants reviewed in Table 6–14, but Volpe [350] identified seizures, in many cases subtle, in 75% of infants with bacterial meningitis. Approximately half of the seizures were focal, and at their onset, they usually were subtle. Focal signs, including hemiparesis; horizontal deviation of the eyes; and cranial nerve deficits involving the seventh, third, and sixth cranial nerves, in that order of frequency, can be identified [350]. Because cranial sutures in the neonate are open and allow for expansion of the intracranial contents and for increasing head size, a full or bulging fontanelle can be absent [448,477]. The presence of a bulging fontanelle is not related to gestational age. Among 72 newborns with gram-negative enteric bacillary meningitis, a bulging fontanelle was seen in 18% of term infants and 17% of preterm infants [23]. Nuchal rigidity, an important sign in older children and adults, is uncommon in neonates [23].

In addition to the physical findings observed in infants with meningitis, several investigators have reported the occurrence of fluid and electrolyte abnormalities associated with inappropriate antidiuretic hormone secretion, including hyponatremia, decreased urine output, and increased weight gain [432,438]. Occasionally, the onset of meningitis has been followed by a transient or persistent diabetes insipidus [477].

Early clinical signs of brain abscess in the newborn are subtle and frequently unnoticed by the physician or parent. Presenting signs include signs of increased intracranial pressure (e.g., emesis, bulging fontanelle, enlarging head size, separated sutures), focal cerebral signs (e.g., hemiparesis, focal seizures), and acute signs of meningitis. Of six infants with brain abscesses described by Hoffman and colleagues [429], two were febrile, two had seizures, and five had increased head size. Other focal infections in the nervous system include pneumococcal endophthalmitis in a neonate with meningitis [478], pseudomonal endophthalmitis in a premature neonate with late-onset sepsis [479], and epidural abscess caused by *S. aureus* in 3-week-old [480], 4-week-old [481], and 7-week-old infants [482].

# DIAGNOSIS

The diagnosis of systemic infection in the newborn is difficult to establish on the basis of clinical findings alone. A history of one or more risk factors for neonatal sepsis associated with the pregnancy and delivery often is associated with early-onset infection, but there can be no clues before the onset of subtle signs in a term infant who develops late-onset sepsis. The extensive list of conditions that must be considered in the differential diagnosis for the various signs that are associated with sepsis or meningitis and noninfectious conditions is presented in Table 6–15. Laboratory tests to assist in the diagnosis of sepsis are discussed in Chapter 36.

## MATERNAL HISTORY

Many infants, particularly infants born prematurely, who develop systemic infection just before or shortly after delivery are born to women who have one or more risk features for early-onset sepsis in their infants. These features include preterm labor, premature rupture of the membranes at any time during gestation, prolonged rupture of membranes, chorioamnionitis, prolonged labor, intrauterine scalp electrodes, and traumatic delivery. The following features are identified by the American College of Obstetrics and Gynecology (ACOG) as the basis for identification of women who should receive intrapartum antibiotic prophylaxis to prevent early-onset group B streptococcal disease:[483,484]

1. Antenatal colonization with GBS
2. Unknown group B streptococcal colonization status and
   a. Preterm labor (<37 weeks' gestation)
   b. Fever during labor (defined by temperature of $\geq 38°$ C [$\geq 100.4°$ F])
   c. Rupture of membranes for 18 or more hours
3. Urine culture that grows GBS during the current pregnancy
4. Prior delivery of a neonate with invasive group B streptococcal infection

## MICROBIOLOGIC TECHNIQUES

Isolation of microorganisms from a usually sterile site, such as the blood, CSF, urine, other body fluids (e.g., peritoneal, pleural, joint, middle ear), or tissues (e.g., bone marrow, liver, spleen) remains the most valid method of diagnosing bacterial sepsis. Infectious agents cultured from the nose, throat, external auditory canal, skin, umbilicus, or stool indicate colonization and can include organisms that cause sepsis, but isolation of a microorganism from these sites does not establish invasive systemic infection. The limited sensitivity, specificity, and predictive value of body surface cultures in the NICU was documented using a database of 24,584 cultures from 3371 infants by Evans and colleagues [485]. These investigators strongly discouraged the use of cultures from

these sites in diagnosing neonatal sepsis because of their poor correlation with the pathogen in the blood and their expense.

## Culture of Blood

Isolation of a pathogenic microorganism from the blood or other body fluid is the only method to establish definitively the diagnosis of neonatal bacteremia/sepsis.

### Methods

Technology has evolved from manually read, broth-based methods to continuously monitored, automated blood culture systems that use enriched media for processing of blood culture specimens. Automated and semiautomated systems for continuous blood culture monitoring are standard in laboratories in the United States [486–488]. Before the widespread use of automated blood-culturing systems, direct plating was the most often employed method of isolating bacteria. Positive cultures were recognized by growth of colonies on agar and provided a rapid means to obtaining quantitative blood culture results from pediatric patients. St. Geme and colleagues [489] used this technique to investigate the distinction of sepsis from contamination in cultures of blood growing CoNS.

### Time to Detection of a Positive Blood Culture

Bacterial growth is evident in most cultures of blood from neonates within 48 hours [490–492]. With use of conventional culture techniques and subculture at 4 and 14 hours, only 4 of 105 cultures that had positive results (one GBS and three S. aureus) required more than 48 hours of incubation [491]. By use of a radiometric technique (BACTEC 460), 40 of 41 cultures that grew GBS and 15 of 16 cultures with *E. coli* were identified within 24 hours [492]. Controlled experiments suggest that delayed entry of the collected blood culture bottle into the automated blood culture machine can significantly prolong the time to positivity for common newborn pathogens [493].

### Optimal Number of Cultures

The optimal number of cultures to obtain for the diagnosis of bacteremia in the newborn is uncertain. A single blood culture from an infant with sepsis can be negative, but most studies suggest a sensitivity of 90% or slightly more. Sprunt [494] suggested the use of two blood cultures "not primarily to increase the yield of organisms . . ." but to "minimize the insecurity and debates over the meaning of the findings." In a study by Struthers and colleagues [95], it was estimated that in 5% of neonates a second blood culture failed to substantiate the presence of CoNS leading to an 8% reduction in antibiotic use. In the high-risk neonate, there is no doubt the need to initiate therapy promptly can make this practice difficult.

### Optimal Volume of Blood

The optimal volume of blood needed to detect bacteremia in neonates has not been determined. Neal and colleagues [495] evaluated the volume of neonatal blood submitted for culture by physicians who were unaware of the study and found that the mean blood volume per patient was 1.05 mL. Dietzman and coworkers [496] suggested that 0.2 mL of blood was sufficient to detect bacteremia caused by *E. coli*. The relationship between colony counts of *E. coli* from blood cultures from infants with sepsis and meningitis and mortality was evaluated. Meningitis occurred only in neonates with more than 1000 colonies of *E. coli* per milliliter of blood. These data of Dietzman and coworkers [496] are supported by experimental results indicating that common pediatric pathogens can be reliably recovered from 0.5 mL of blood even when cultured at blood-to-broth ratios of 1:100 [497,498]. Several more recent studies have found, however, that in the circumstance of low inoculum bacteremia (<10 colony-forming units/mL of blood), the collection of only 0.5 mL of blood proved inadequate for the reliable detection of common pathogens [499–502]. If one blood culture is to be collected before antimicrobial therapy is initiated, a volume of 1 mL or more seems to ensure the greatest sensitivity.

### Cultures of Blood from Umbilical Vessels and Intravascular Catheters

Umbilical vessel and intravascular catheters are essential in the care of neonates in the NICU and are preferred blood culture sampling sites [503–505]. Results of cultures of blood obtained from indwelling umbilical or central venous catheters can present ambiguities in interpretation (e.g., contamination versus catheter colonization versus systemic infection). Obtaining blood cultures from a peripheral vessel and catheters in an ill-appearing neonate is useful in the interpretation of results. A prospective study of semiquantitative catheter tip cultures in a Brazilian NICU found that a cutoff point of approximately 100 colony-forming units was predictive of clinically significant catheter-related infections, of which CoNS accounted for 75% of cases [506].

### Distinguishing Clinically Important Bacteremia from Blood Culture Contamination

The increased use of intravascular catheters in neonates has resulted in an increase in the incidence of bacteremia, particularly bacteremia caused by CoNS, and uncertainty regarding the significance of some results. Investigators have considered criteria based on clinical signs and microbiologic factors.

Yale investigators [6] used the following criteria to define the role of commensal organisms in neonatal sepsis: one major clinical sign, such as apnea, bradycardia, or core temperature greater than 38° C or less than 36.5° C documented at the time the blood culture was obtained, plus another blood culture positive for the same organism obtained within 24 hours of the first or an intravascular access device in place before major clinical signs occurred. Some microbiologic features can be useful in differentiating sepsis from contamination, as follows:

1. *Time to growth in conventional media*: The longer the time needed to detect growth (>2 to 3 days), the more likely that skin or intravascular line contamination was present.

2. *Number of cultures positive*: If peripheral and intravascular catheter specimens are positive, the presence of the organism in the blood is likely; if the catheter specimen alone is positive, intravascular line colonization may have occurred; if multiple cultures from an indwelling vascular catheter are positive, or if a single culture is positive and the patient has had a clinical deterioration, a bloodstream infection must be presumed.
3. *Organism type*: Organisms that are part of skin flora (e.g., diphtheroids, nonhemolytic streptococci, CoNS) suggest contamination in certain cases as described previously, whereas known bacterial pathogens must be considered to be associated with sepsis. Contamination is more likely when multiple species grow in one blood culture bottle, different species grow in two bottles, or only one of several cultures before or during antimicrobial therapy is positive.
4. *Clinical signs*: If the infant is well without use of antibiotics, growth of a commensal organism from a blood culture is more likely to be a contaminant.

In an attempt to resolve the question of sepsis versus contamination, investigators have used multiple-site blood cultures [507], comparisons of results of cultures of blood and cultures of skin at the venipuncture site [508], and quantitative blood cultures [491]. These techniques are of investigational interest, but the results do not suggest that any one is of sufficient value to be adopted for clinical practice. Healy and colleagues [509] suggest that isolation of CoNS of the same species or antimicrobial susceptibility from more than one blood culture or from one blood culture obtained from an indwelling catheter or a peripheral vessel and a normally sterile body site represents true infection if the patient is a premature infant with signs of clinical sepsis. At present, management of a sick premature infant, especially a very low birth weight infant, with a positive blood culture for CoNS requires that the organism be considered a pathogen and managed with appropriate antimicrobial agents. If the infant is well, the microbiologic results given earlier should be considered in the decision to continue or discontinue use of an antimicrobial agent. Another culture of blood should be obtained when the initial culture result is ambiguous.

## Buffy-Coat Examination

The rapid diagnosis of bacteremia by identification of microorganisms in the buffy leukocyte layer of centrifuged blood is a method used for many years and has been evaluated for use in newborn infants [510–516]. By using Gram and methylene blue stains of the buffy-coat preparation, immediate and accurate information was obtained for 37 (77%) of 48 bacteremic, clinically septic infants in the four studies [511–513,515]. Positive results were found for gram-positive and gram-negative organisms. In contrast to findings reported for adult populations [517], there were no false-positive results among almost 200 infants with negative blood cultures. Failure to identify organisms was attributed to extreme neutropenia in several patients.

The large inoculum of microorganisms in the blood of neonates with sepsis most probably explains the excellent sensitivity of leukocyte smears. Smears can be positive with 50 colonies per milliliter of *S. aureus* in the peripheral blood; approximately 50% of neonates with *E. coli* bacteremia have higher concentrations [496]. *Candida* and *S. epidermidis* septicemia in young infants also have been diagnosed by this method [518–521]. Rodwell and associates reported that bacteria were identified in peripheral blood smears in 17 of 19 infants with septicemia; however, they [522] were able to identify bacteria in direct blood smears, however, for only 4 of 24 bacteremic neonates. It is likely that the disparity in these results reflects differences in patient populations or distribution of etiologic agents or both. Buffy-coat examination of blood smears has been infrequently used in laboratories since the introduction of automated systems for continuous blood culture monitoring.

## Culture of Urine

Infants with sepsis can have a urinary tract origin or a concomitant urinary tract infection. The yield from culture of urine is low in early-onset sepsis and most often reflects metastatic spread to the bladder from the bacteremia, but in late-onset infection, the yield is substantially higher. Visser and Hall [523] found positive cultures of urine in only 1.6% of infants with early-onset sepsis compared with 7.4% of infants with late-onset sepsis. DiGeronimo [524] performed a chart review of 146 clinically septic infants who had cultures of blood and urine. Of 11 infants with positive blood cultures, only one infant with GBS bacteremia had a positive urine culture. These data suggest that cultures of urine yield very limited information about the source of infection in infants with signs of sepsis before age 7 days. In contrast, urine should be collected for culture from infants with suspected late-onset sepsis before initiation of antimicrobial therapy. The presence of elevated leukocyte counts ($\geq$10 per high-power field) in urine of infants less than 90 days of age is an accurate predictor of urinary tract infections complicated by bacteremia [525].

Because of the difficulty in collecting satisfactory clean-voided specimens of urine from newborns, bladder catheterization or suprapubic needle aspiration of bladder urine frequently is performed. These methods are simple and safe, and suprapubic bladder aspiration avoids the ambiguities inherent in urine obtained by other methods [526–528]. If a suprapubic aspirate cannot be performed for technical or medical reasons, catheterization is a satisfactory method of obtaining urine, although ambiguous results can occur because of contamination from the urethra, especially in very low birth weight neonates. Application of a clinical pain scoring system employing a blinded observer and video recording found suprapubic aspiration to produce more discomfort than transurethral catheterization in female and circumcised male infants younger than 2 months of age [529].

## Cultures of Tracheal Aspirates and Pharynx

Because of the association of pneumonia and bacteremia, investigators have sought to determine the risk of sepsis on the basis of colonization of the upper respiratory tract.

Lau and Hey [530] found that among ventilated infants who became septic, the same organism usually was present in cultures of tracheal aspirate and blood. Growth of a bacterial pathogen from a tracheal aspirate culture does not predict which infants will develop sepsis, however. Similarly, cultures of the pharynx or trachea do not predict the causative organism in the blood of a neonate with clinical sepsis [531]. A review of the literature by Srinivasan and Vidyasagar [532] suggests endotracheal aspirates are of poor sensitivity (approximately 50%), modest specificity (approximately 80%), and poor positive predictive value. Unless the patient has a change in respiratory status documented clinically and radiographically, routine use of cultures from the pharynx or trachea provide low diagnostic yield and seem unjustified given their expense.

## Diagnostic Needle Aspiration and Tissue Biopsy

Direct aspiration of tissues or body fluids through a needle or catheter is used for the diagnosis of a wide variety of infectious and noninfectious diseases [533]. Aspiration of an infectious focus in lung, pleural space, middle ear, pericardium, bones, joints, abscess, and other sites provides immediate and specific information to guide therapy. Biopsy of the liver or bone marrow can assist in diagnosing occult infections, but this rarely is necessary.

## Autopsy Microbiology

Two factors must be considered in interpreting bacterial cultures obtained at autopsy: the frequent isolation of organisms usually considered to be nonpathogenic and the difficulty of isolating fastidious organisms such as anaerobic bacteria. To minimize these problems, it is important that specimens be collected with proper aseptic technique and as early as possible after death.

It is a common belief that organisms in the intestinal and respiratory tracts gain access to tissues after death, but it also is possible that bacteremia occurs shortly before death and is not a postmortem phenomenon. Eisenfeld and colleagues [534] identified the same organisms in specimens obtained before and within 2 hours after death. Confusion in the interpretation of results of bacteriologic cultures often is obviated by the review of slides prepared directly from tissues and fluids. If antimicrobial treatment was administered before death, organisms can be observed on a smear even though they are not viable. Pathogens would be expected to be present in significant numbers and accompanied by inflammatory cells, whereas contaminants or organisms that invade tissues after death, if they are seen, would be present in small numbers with no evidence of an inflammatory process [535,536].

## Rapid Techniques for Detection of Bacterial Antigens in Body Fluid Specimens

In the 1970s, the limulus lysate assay for detection of endotoxin produced by gram-negative bacteria based on a gelation reaction between lysates of *Limulus* (horseshoe crab) amebocytes and bacterial endotoxin was investigated for diagnosis of neonatal meningitis with equivocal results [537–541]. Counterimmunoelectrophoresis also was used successfully for detecting the capsular polysaccharide antigens of various pathogenic bacteria, including *S. pneumoniae*, *N. meningitidis*, *H. influenzae*, and GBS (see Chapter 12) in CSF, serum, and urine. Less complex and more rapid detection methods have replaced these two assays.

Latex agglutination detection now is preferred because of its speed, simplicity, and greater sensitivity for selected organisms. Kits designed to detect cell wall or capsular or cell wall antigen released into body fluids are commercially available. Latex agglutination assays have been shown to be of potential benefit in early detection of bacterial antigens in CSF of patients with acute meningitis, which may be of increased importance in the era of intrapartum antibiotic prophylaxis and its potential interference with culture yield. Among the prevalent bacterial pathogens in neonatal infections, only GBS is routinely analyzed by latex agglutination. *N. meningitidis* group B shares a common capsular antigen, however, with the neonatal meningitis pathogen *E. coli* serotype K1, which should allow cross-identification of the latter using a meningococcal latex reagent [542]. The sensitivity of latex agglutination methods for identifying infants with group B streptococcal meningitis ranges from 73% to 100% for CSF and 75% to 84% for urine [543]. Possible cross-reactions have occurred when concentrated urine was tested. GBS cell wall antigen can occasionally cross-react with antigens from *S. pneumoniae*, CoNS, enterococci, and gram-negative enteric bacteria, including *P. mirabilis* and *E. cloacae*.

False-positive results in urine for a positive latex agglutination test for GBS often were caused by contamination of bag specimens of urine with the streptococci from rectal or vaginal colonization [544]. The poor specificity of GBS antigen detection methods used with urine led to the U.S. Food and Drug Administration (FDA) recommendation in 1996 that these methods not be employed except for testing of CSF and serum.

## Lumbar Puncture and Examination of Cerebrospinal Fluid

Because meningitis can accompany sepsis with no clinical signs to differentiate between bacteremia alone and bacteremia with meningitis, a lumbar puncture should be considered for examination of CSF in any neonate before initiation of therapy. Of infants with sepsis, 15% have accompanying meningitis. The overall incidence of bacterial meningitis is less than 1 case per 1000 infants, but the incidence for low birth weight (<2500 g) infants or premature infants is severalfold higher than the incidence for term infants. Data from NICHD Neonatal Research Network surveyed 9641 very low birth weight infants who survived 3 days or more: 30% had one or more lumbar punctures, and 5% of infants who had lumbar puncture had late-onset meningitis [545]. For the diagnosis of some noninfectious CNS diseases in neonates (e.g., intracranial hemorrhage), cranial ultrasonography and, occasionally, computed tomography (CT) or magnetic resonance imaging (MRI) are the techniques of choice. Among infants with hypoxic-ischemic encephalopathy,

lumbar puncture should be considered only for infants in whom meningitis is a possible diagnosis.

Some investigators suggest that too many healthy term infants have a diagnostic evaluation for sepsis, including lumbar puncture, based solely on maternal risk features and that lumbar puncture rarely provides clinically useful information. Other investigators have questioned the role of lumbar puncture on admission in the premature infant with respiratory distress and found that the yield of the procedure is very low [546–548]. Of more than 1700 infants with respiratory distress syndrome evaluated for meningitis, bacterial pathogens were identified in CSF of only 4. Three of the four infants with meningitis were bacteremic with the same pathogen [548].

A large, retrospective study assessed the value of lumbar puncture in the evaluation of suspected sepsis during the first week of life and found that bacteria were isolated from 9 of 728 CSF specimens, but only one infant was believed to have bacterial meningitis [549]. Fielkow and colleagues [550] found no cases of meningitis among 284 healthy-appearing infants who had lumbar puncture performed because of maternal risk factors, whereas 2.5% of 799 neonates with clinical signs of sepsis had meningitis regardless of maternal risk factors. The value of lumbar puncture has been established for infants with clinical signs of sepsis, but lumbar puncture performed because of maternal risk features in a healthy-appearing neonate is less likely to be useful.

The considerations are quite different for very low birth weight neonates (400 to- 1500 g), as documented in a study by Stoll and colleagues [545] performed through NICHD Neonatal Research Network. One third (45 of 134) of these high-risk neonates with meningitis has negative blood cultures. Lower gestational age and prior sepsis were important risk factors for development of meningitis, which carried a significant risk of mortality compared with uninfected infants (23% versus 2%). These results indicate the critical importance of lumbar puncture and suggest that meningitis may be significantly underdiagnosed in very low birth weight infants [545].

### Method of Lumbar Puncture

Lumbar puncture is more difficult to perform in neonates than in older children or adults; traumatic lumbar punctures resulting in blood in CSF are more frequent, and care must be taken in the infant who is in respiratory distress. Gleason and colleagues [551] suggested that the procedure be performed with the infant in the upright position or, if performed in the flexed position, be modified with neck extension. Pinheiro and associates [552] evaluated the role of locally administered lidocaine before lumbar puncture and found that the local anesthesia decreased the degree of struggling of the infant. Other investigators concluded, however, that local anesthesia failed to influence physiologic changes in the neonate undergoing lumbar puncture [553]. Fiser and colleagues [554] suggested that the administration of oxygen before lumbar puncture prevents most hypoxemia resulting from this procedure in infants.

The physician can choose to withhold or delay lumbar puncture in some infants who would be placed at risk for cardiac or respiratory compromise by the procedure. Weisman and colleagues [555] observed that transient hypoxemia occurred during lumbar puncture performed in the lateral position (i.e., left side with hips flexed to place knees to chest), but occurred less frequently when the infant was in a sitting position or modified lateral position (i.e., left side with hips flexed to 90 degrees). Reasons for withholding lumbar puncture in older children, such as signs of increased intracranial pressure, signs of a bleeding disorder, and infection in the area that the needle would traverse to obtain CSF, are less likely to be concerns in the neonate.

Ventricular puncture should be considered in an infant with meningitis who does not respond clinically or microbiologically to antimicrobial therapy because of ventriculitis, especially with obstruction between the ventricles and lumbar CSF. Ventriculitis is diagnosed on the basis of elevated white blood cell count (>100 cells/mm$^3$) or identification of bacteria by culture, Gram stain, or antigen detection. Ventricular puncture is a potentially hazardous procedure and should be performed only by a physician who is an expert in the technique.

### If a Lumbar Puncture Is Not Performed

Is it sufficient to culture only blood and urine for the diagnosis of neonatal bacterial meningitis? Visser and Hall [556] showed that the blood culture was sterile when CSF yielded a pathogen in 6 (15%) of 39 infants with bacterial meningitis. Franco and colleagues [557] reported that in 26 neonates with bacterial meningitis, only 13 had a positive blood culture. In surveys from two large databases—NICUs managed by the Pediatrix Medical Group [558] and NICHD Neonatal Research Network [545]—results were similar: One third of infants at 34 or more weeks estimated gestation with meningitis and one third of very low birth weight neonates with meningitis had negative blood cultures. A significant number of infants with meningitis do not have this diagnosis established unless lumbar puncture is performed.

Ideally, lumbar puncture should be performed before the initiation of antimicrobial therapy, but there are alternative strategies for infants who may not tolerate the procedure. If the physician believes that lumbar puncture would endanger the infant with presumed sepsis and meningitis, therapy should be initiated after blood (and urine for late-onset illness) is obtained for culture. After the infant is stabilized, lumbar puncture should be performed. Even several days after the start of antibiotic therapy, CSF pleocytosis and abnormal CSF chemistry assays usually should identify the presence or absence of an inflammatory reaction, although CSF culture may be sterile.

### Examination of Cerebrospinal Fluid

The cell content and chemistry of CSF of healthy newborn infants differ from those of older infants, children, and adults (Table 6–16). The values vary widely during the first weeks of life, and the normal range must be considered in evaluation of CSF in infants suspected to have meningitis [559–568]. The cell content in CSF of a neonate is higher than in older infants. Polymorphonuclear leukocytes often are present in CSF of normal newborns,

**TABLE 6–16** Hematologic and Chemical Characteristics of Cerebrospinal Fluid in Healthy Term Newborns: Results of Selected Studies

| Study (Year) | No. Patients | Age (Days) | White Blood Cells (mm³)* | Neutrophils (mm³)* | Glucose (mg/dL)* | Protein (mg/dL)* |
|---|---|---|---|---|---|---|
| Naidoo[559] (1968) | 135 | 1 | 12 (0-42) | 7 (0-26) | 48 (38-64) | 73 (40-148) |

whereas more than a single polymorphonuclear neutrophil in CSF of older infants or children should be considered abnormal. Similarly, protein concentration is higher in preterm than in term infants and highest in very low birth weight infants (Table 6–17) [568].

In term infants, total protein concentration decreases with age, reaching values of healthy older infants (<40 mg/dL) before the third month of life. In low birth weight infants or preterm infants, CSF leukocyte and protein concentrations decline with postnatal age, but may not decline to normal values for older infants for several months after birth [569]. CSF glucose levels are lower in neonates than in older infants and can be related to lower concentrations of glucose observed in blood. Healthy term infants may have blood glucose levels of 30 mg/dL, and preterm infants may have levels of 20 mg/dL [568]. The physiologic basis for the higher concentration of protein and the increased numbers of white blood cells in CSF of healthy, uninfected preterm and term infants is unknown. Explanations that have been offered include possible mechanical irritation of the meninges during delivery and increased permeability of the blood-brain barrier.

In nearly all of the studies of CSF in newborns, "normal" or "healthy" refers to the absence of clinical manifestations at the time of examination of CSF. Only the study by Ahmed and colleagues [562] included in the definition of normal the absence of viral infection, defined by lack of evidence of cytopathic effect in five cell lines and negative polymerase chain reaction for enteroviruses. None of the studies included information about the health of the infant after the newborn period. It now is recognized that infants with congenital infections, such as rubella, cytomegalovirus infection, toxoplasmosis, acquired immunodeficiency syndrome (AIDS), and syphilis, can have no signs of illness during the newborn period. Observations of these infants over the course of months or years can reveal abnormalities that are inapparent at birth. Until more data are available, it seems prudent to observe carefully infants with white blood cells greater than 20 per mm³ or protein level greater than 100 mg/dL in CSF and, if clinical signs indicate, to obtain paired serum samples for serologic assays and viral cultures from body fluids or tissues for congenital CNS infections (i.e., *T. gondii*, rubella virus, cytomegalovirus, herpes simplex virus, human immunodeficiency virus [HIV], and *T. pallidum*).

In newborns with bacterial meningitis, there can be thousands of white blood cells in CSF, and polymorphonuclear leukocytes predominate early in the course of the disease [20,560]. The number of white blood cells in CSF can vary greatly in infants with gram-negative and gram-positive meningitis. The median number of cells per cubic millimeter in CSF of 98 infants with gram-negative

meningitis was more than 2000 (range 6 to 40,000), whereas the median number of cells per cubic millimeter in 21 infants with group B streptococcal meningitis was less than 100 (range 8 to >10,000) [560]. The concentration of glucose in CSF usually is less than two thirds of the concentration in blood. The concentration of protein can be low (<30 mg/dL) or very high (>1000 mg/dL). CSF parameters observed in the healthy term neonate can overlap with those observed in the infant with meningitis.

A Gram stain smear of CSF should be examined for bacteria, and appropriate media should be inoculated with the CSF specimen. Sarff and colleagues [560] detected organisms in Gram stain smears of CSF in 83% of infants with group B streptococcal meningitis and in 78% of infants with gram-negative meningitis. After initiation of appropriate antimicrobial therapy, gram-positive bacteria usually clear from CSF within 36 hours, whereas in some patients with meningitis caused by gram-negative enteric bacilli, cultures can remain positive for many days [567].

Microorganisms can be isolated from CSF that has normal white blood cell and chemistry test values. Visser and Hall [556] reported normal CSF parameters (cell count <25; protein level <200 mg/dL) in 6 (15%) of 39 infants with culture-proven meningitis. Subsequent examination of CSF identified an increase in the number of cells and in the protein level. Presumably, the initial lumbar puncture was performed early in the course of meningitis before an inflammatory response occurred. Other investigators reported isolation of enterovirus [570] and *S. pneumoniae* [571] from the CSF of neonates in the absence of pleocytosis.

Identification of bacteremia without meningitis defined by the absence of pleocytosis or isolation of a pathogen from culture of CSF can be followed by meningeal inflammation on subsequent examinations. Sarman and colleagues [572] identified six infants with gram-negative bacteremia and initial normal CSF who developed evidence of meningeal inflammation 18 to 59 hours after the first examination. Although the investigators suggest that a diagnosis of gram-negative bacteremia in the neonate warrants repeat lumbar puncture to identify the optimal duration of therapy, this recommendation could be broadened to include all infants with bacteremia and initial negative studies of CSF. Dissemination of the organisms from the blood to the meninges can occur after the first lumbar puncture before sterilization of the blood by appropriate antimicrobial therapy occurs. This dissemination is especially likely to occur in neonates with intense bacteremia where sterilization by β-lactam agents (i.e., third-generation cephalosporins) depends on the inoculum.

Smith and colleagues [573] performed a large cohort study of CSF parameters in preterm neonates with meningitis. Analysis of first lumbar puncture of 4632 neonates less than 34 weeks' gestation found significant differences in culture-proven meningitis cases versus controls in CSF leukocyte count (110 cells/mm$^3$ versus 6 cells/mm$^3$), total protein (217 mg/dL versus 130 mg/dL), and glucose (43 mg/dL versus 49 mg/dL). The sensitivity for predicting meningitis was only 71%, however, for CSF leukocyte count greater than 25 cells/mm$^3$, 61% for CSF protein greater than 170 mg/dL, and 32% for CSF glucose less than 24 mg/dL. The positive predictive value for each of these parameters was low (4% to 10%), emphasizing the critical need for CSF culture to establish the diagnosis of meningitis. In terms of excluding meningitis, a normal CSF protein was the most useful parameter because 96% of premature neonates with meningitis had CSF protein greater than 90 mg/dL [573].

Investigators have sought a sensitive and specific CSF metabolic determinant of bacterial meningitis with little success. Among products that have been evaluated and found to be inadequate to distinguish bacterial meningitis from other neurologic disease (including cerebroventricular hemorrhage and asphyxia) are γ-aminobutyric acid [574], lactate dehydrogenase [575], and creatine kinase brain isoenzyme [576]. Cyclic-3′,5′-adenosine monophosphate was elevated in CSF of neonates with bacterial meningitis compared with CSF of infants who had nonbacterial meningitis or a control group [577]. Elevated CSF concentrations of C-reactive protein have been reported for infants older than 4 weeks with bacterial meningitis [578]; however, the test was found to be of no value in neonates [579,580]. Current investigations of the proinflammatory cytokines interleukin-6 and interleukin-8 indicate that there is a cytokine response in CSF after birth asphyxia and that these assays are not useful in detecting infants with meningitis [581,582].

### Traumatic Lumbar Puncture

A traumatic lumbar puncture can result in blood in CSF and can complicate the interpretation of the results for CSF white blood cell count and chemistries. Schwersenski and colleagues [549] found that 13.8% of 712 CSF specimens obtained during the first week of life were bloody and that an additional 14.5% were considered inadequate for testing.

If the total number of white blood cells compared with the number of red blood cells exceeds the value for whole blood, the presence of CSF pleocytosis is suggested. Some investigators have found that the observed white blood cell counts in bloody CSF were lower than would be predicted based on the ratio of white blood cells to red blood cells in peripheral blood; the white blood cells lyse more rapidly than red blood cells, or the number of white blood cells is decreased for other reasons [583–586]. Several formulas have been used in an attempt to interpret cytologic findings in CSF contaminated by blood [587–589]. None of the corrections applied to bloody CSF can be used with confidence, however, for excluding meningitis in the neonate [590–592]. In a cohort study of lumbar punctures performed at 150 neonatal units from 1997-2004, 39.5% (2519 of 6374) were traumatic, and 50 of these infants were found to have meningitis by culture. The authors found that adjustment of the leukocyte count to account for blood contamination resulted in loss of sensitivity and only marginal gain in specificity, and would not aid in the diagnosis of bacterial (or fungal) meningitis [593].

Protein in CSF usually is elevated after a traumatic lumbar puncture because of the presence of red blood cells. It has been estimated in older children and adults

that an increase of 1 mg/dL in CSF protein occurs for every 1000 red blood cells/μL. The concentration of glucose does not seem to be altered by blood from a traumatic lumbar puncture; a low CSF glucose concentration should be considered an important finding even when associated with a traumatic lumbar puncture.

Because a "bloody tap" is difficult to interpret, it may be valuable to repeat the lumbar puncture 24 to 48 hours later. If the results of the second lumbar puncture reveal a normal white blood cell count, bacterial meningitis can be excluded. Even if performed without trauma or apparent bleeding, CSF occasionally can be ambiguous because white blood cells can be elicited by the irritant effect of blood in CSF.

### *Brain Abscess*

Brain abscess is a rare entity in the neonate, usually complicating meningitis caused by certain gram-negative bacilli. CSF in an infant with a brain abscess can show a pleocytosis of a few hundred cells with a mononuclear predominance and an elevated protein level. Bacteria may not be seen by Gram stain of CSF if meningitis is not present. Sudden clinical deterioration and the appearance of many cells (>1000/mm$^3$), with most polymorphonuclear cells, suggest rupture of the abscess into CSF.

## LABORATORY AIDS

Historically, aids in the diagnosis of systemic and focal infection in the neonate include peripheral white blood cell and differential counts, platelet counts, acute-phase reactants, blood chemistries, histopathology of the placenta and umbilical cord, smears of gastric or tracheal aspirates, and diagnostic imaging studies. New assays for diagnosis of early-onset sepsis, including serum concentrations of neutrophil CD 11b [594], granulocyte colony-stimulating factor [595], interleukin receptor antagonist [596], interleukin-6 [597–599], procalcitonin [600–602], serum amyloid A [603], and prohepcidin [604], show promise for increased sensitivity and specificity compared with other laboratory assessments, such as white blood cell count, absolute neutrophil count, and acute-phase reactants. Proinflammatory cytokines, including interleukin-1, interleukin-6, and tumor necrosis factor-α, have been identified in serum and CSF in infants after perinatal asphyxia, raising doubts about the specificity of some of these markers [581,582,605,606]. Mehr and Doyle [607] reviewed the more recent literature on cytokines as aids in the diagnosis of neonatal bacterial sepsis. These assays and procedures are discussed in detail in Chapter 36.

Attention has focused more recently on the use of real-time polymerase chain reaction technologies, often based on the 16S ribosomal RNA sequence of leading pathogens, as a tool for the accelerated culture-independent diagnosis of neonatal sepsis. Compared with the gold standard of blood culture, the evaluation of sensitivity and specificity of PCR technologies and their consequent clinical utility has ranged from equivocal [608,609] to highly promising [610,611]. Continued rapid advances in nucleic acid–based diagnostics are certain to be explored in this important clinical arena.

# MANAGEMENT

If the maternal history or infant clinical signs suggest the possibility of neonatal sepsis, blood and CSF (all infants) and cultures of urine and other clinically evident focal sites should be collected (all infants with suspected late-onset infection). If respiratory abnormalities are apparent or respiratory status has changed, a radiograph of the chest should be performed. Because the clinical manifestations of sepsis can be subtle, the progression of the disease can be rapid, and the mortality rate remains high compared with mortality for older infants with serious bacterial infection, presumptive treatment should be initiated promptly. Many infants who have a clinical course typical of bacterial sepsis are treated empirically because of the imperfect sensitivity of a single blood culture in the diagnosis of sepsis.

## CHOICE OF ANTIMICROBIAL AGENTS

### Initial Therapy for Presumed Sepsis

The choice of antimicrobial agents for the treatment of suspected sepsis is based on knowledge of the prevalent organisms responsible for neonatal sepsis by age of onset and hospital setting and on their patterns of antimicrobial susceptibility. Initial therapy for the infant who develops clinical signs of sepsis during the first few days of life (early-onset disease) must include agents active against gram-positive cocci, particularly GBS, other streptococci, and *L. monocytogenes*, and gram-negative enteric bacilli. Treatment of the infant who becomes septic while in the nursery after age 6 days (late-onset disease) must include therapy for hospital-acquired organisms, such as *S. aureus*, gram-negative enteric bacilli, CoNS (in very low birth weight infants), and occasionally *P. aeruginosa*, and for maternally acquired etiologic agents.

GBS continue to exhibit significant in vitro susceptibility to penicillins and cephalosporins. Of 3813 case isolates in active population-based surveillance by the CDC from 1996-2003, all were sensitive to penicillin, ampicillin, cefazolin, and vancomycin [612]. New reports in the United States and Japan have identified GBS strains with reduced β-lactam susceptibility, however, and first-step mutations in the PBPx2 protein reminiscent of the emergence of β-lactam resistance in pneumococci decades ago [613,614]. In the CDC surveillance, GBS resistance to clindamycin (15%) and erythromycin (30%) also was noted to be increasing [612].

In vitro studies [615–617] and experimental animal models of bacteremia [618,619] indicate that the bactericidal activity of ampicillin and penicillin against GBS and *L. monocytogenes* is enhanced by the addition of gentamicin (synergy). Some physicians prefer to continue the combination of ampicillin and gentamicin for 48 to 72 hours, but when GBS is identified as the etiologic agent, the drug of choice for therapy is penicillin administered intravenously for the remainder of the treatment regimen. There are no clinical data to indicate that continuing an aminoglycoside in combination with a penicillin after 72 hours results in more rapid recovery or improved outcome for infected neonates (see Chapter 12).

Most strains of *S. aureus* that cause disease in neonates produce β-lactamase and are resistant to penicillin G and

ampicillin. Many of these organisms are susceptible to penicillinase-resistant penicillins, such as nafcillin, and to first-generation cephalosporins. Methicillin-resistant staphylococci that are resistant to other penicillinase-resistant penicillins and cephalosporins have been encountered in many nurseries in the United States. Antimicrobial susceptibility patterns must be monitored by surveillance of staphylococcal strains causing infection and disease in each NICU. Bacterial resistance must be considered whenever staphylococcal disease is suspected or confirmed in a patient, and empirical vancomycin therapy should be initiated until the susceptibility pattern of the organism is known. Virtually all staphylococcal strains isolated from neonates have been susceptible to vancomycin. Synergistic activity is provided by the combination of an aminoglycoside (see Chapter 14). Vancomycin-resistant and glycopeptide-resistant *S. aureus* has been reported from Japan and the United States, but none of these strains has been isolated from neonates.

CoNS can cause systemic infection in very low birth weight infants and in neonates with or without devices such as an intravascular catheter or a ventriculoperitoneal shunt. Vancomycin is the drug of choice for treatment of serious CoNS infections. If daily cultures from an indwelling device continue to grow CoNS, removal of the foreign material probably is necessary to cure the infection.

*Enterococcus* species are only moderately susceptible to penicillin and highly resistant to cephalosporins. Optimal antimicrobial therapy for neonatal infections caused by *Enterococcus* includes ampicillin or vancomycin in addition to an aminoglycoside, typically gentamicin or tobramycin.

*L. monocytogenes* is susceptible to penicillin and ampicillin and resistant to cephalosporins. Ampicillin is the preferred agent for treating *L. monocytogenes*, although an aminoglycoside can be continued in combination with ampicillin if the patient has meningitis. Specific management of *L. monocytogenes* infection is discussed in Chapter 13.

The choice of antibiotic therapy for infections caused by gram-negative bacilli depends on the pattern of susceptibility for these isolates in the nursery that cares for the neonate. These patterns vary by hospital or community and by time within the same institution or community. Although isolates from neonates should be monitored to determine the emergence of new strains with unique antimicrobial susceptibility patterns, the general pattern of antibiotic susceptibility in the hospital is a good guide to initial therapy for neonates. Aminoglycosides, including gentamicin, tobramycin, netilmicin, and amikacin, are highly active in vitro against virtually all isolates of *E. coli*, *P. aeruginosa*, *Enterobacter* species, *Klebsiella* species, and *Proteus* species.

### Role of Third-Generation Cephalosporins and Carbapenems

The third-generation cephalosporins, cefotaxime, ceftriaxone, and ceftazidime, possess attractive features for therapy for bacterial sepsis and meningitis in newborns, including excellent in vitro activity against GBS and *E. coli* and other gram-negative enteric bacilli. Ceftazidime is highly active in vitro against *P. aeruginosa*. None of the cephalosporins is active against *L. monocytogenes* or *Enterococcus*, and activity against *S. aureus* is variable. The third-generation cephalosporins provide concentrations of drug at most sites of infection that greatly exceed the minimum inhibitory concentrations of susceptible pathogens, and there is no dose-related toxicity. Clinical and microbiologic results of studies of sepsis and meningitis in neonates suggest that the third-generation cephalosporins are comparable to the traditional regimens of penicillin and an aminoglycoside (see Chapter 37) [620–623]. Because ceftriaxone can displace bilirubin from serum albumin, it is not recommended for use in neonates unless it is the only agent effective against the bacterial pathogen. Meropenem is a broad-spectrum carbapenem antibiotic with extended-spectrum antimicrobial activity including *P. aeruginosa* and excellent CSF penetration that appears safe and efficacious in the neonate for treatment of most nosocomial gram-negative pathogens [624].

The rapid development of resistance of gram-negative enteric bacilli when cefotaxime is used extensively for presumptive therapy for neonatal sepsis suggests that extensive use of third-generation or fourth-generation cephalosporins can lead to rapid emergence of drug-resistant bacteria in nurseries [625]. Also of concern, studies have identified a principal risk factor for development of invasive infection with *Candida* and other fungi in preterm neonates to be extended therapy with third-generation cephalosporins [626,627]. Empirical use of cefotaxime in neonates should be restricted to infants with evidence of meningitis or with gram-negative sepsis. Continued cefotaxime therapy should be limited to infants with gram-negative meningitis caused by susceptible organisms or infants with ampicillin-resistant enteric infections [628].

## CURRENT PRACTICE

The combination of ampicillin and an aminoglycoside, usually gentamicin or tobramycin, is suitable for initial treatment of presumed early-onset neonatal sepsis [629]. If there is a concern for endemic or epidemic staphylococcal infection, typically occurring beyond 6 days of age, the initial treatment of late-onset neonatal sepsis should include vancomycin.

The increasing use of antibiotics, particularly in NICUs, can result in alterations in antimicrobial susceptibility patterns of bacteria and can necessitate changes in initial empirical therapy. This alteration of the microbial flora in nurseries where the use of broad-spectrum antimicrobial agents is routine supports recommendations from the CDC for the judicious use of antibiotics. The hospital laboratory must regularly monitor isolates of pathogenic bacteria to assist the physician in choosing the most appropriate therapy. The clinical pharmacology and dosage schedules of the various antimicrobial agents considered for neonatal sepsis are provided in Chapter 37.

## CONTINUATION OF THERAPY WHEN RESULTS OF CULTURES ARE AVAILABLE

The choice of antimicrobial therapy should be reevaluated when results of cultures and susceptibility tests become available. The duration of therapy depends on

the initial response to the appropriate antibiotics, but should be 10 days, with sepsis documented by positive culture of blood and minimal or absent focal infection. The usual duration of therapy for infants with meningitis caused by GBS gram-negative enteric bacilli is 21 days. In complicated cases of neonatal meningitis, the proper duration of therapy may be prolonged and is best determined in consultation with an infectious diseases specialist.

The third-generation cephalosporins, cefotaxime, ceftriaxone, and ceftazidime, have important theoretical advantages for treatment of sepsis or meningitis compared with therapeutic regimens that include an aminoglycoside. In contrast to the aminoglycosides, third-generation cephalosporins are not associated with ototoxicity and nephrotoxicity. Little toxicity from aminoglycosides occurs when use is brief, however, or, when continued for the duration of therapy, if serum trough levels are maintained at less than 2 μg/mL. Because cephalosporins have no dose-related toxicity, measurements of serum concentrations, which are required with the use of aminoglycosides beyond 72 hours or in infants with renal insufficiency, are unnecessary. Routine use of cephalosporins for presumptive sepsis therapy in neonates often leads to problems with drug-resistant enteric organisms, however. Extensive use of third-generation cephalosporins in the nursery could result in the emergence of resistance caused by de-repression of chromosomally mediated β-lactamases [630].

Cefotaxime is preferred to other third-generation cephalosporins for use in neonates because it has been used more extensively [621–623] and because it does not affect the binding of bilirubin [630,631]. Ceftazidime or meropenem in combination with an aminoglycoside should be used in therapy for *P. aeruginosa* meningitis because of excellent in vitro activity and good penetration into CSF. Use of ceftriaxone in the neonate should be determined on a case-by-case basis because of its ability to displace bilirubin from serum albumin and result in biliary sludging.

## MANAGEMENT OF AN INFANT WHOSE MOTHER RECEIVED INTRAPARTUM ANTIMICROBIAL AGENTS

Antimicrobial agents commonly are administered to women in labor who have risk factors associated with sepsis in the fetus, including premature delivery, prolonged rupture of membranes, fever, or other signs of chorioamnionitis or group B streptococcal colonization. Antimicrobial agents cross the placenta and achieve concentrations in fetal tissues that are parallel to concentrations achieved in other well-vascularized organs. Placental transport of antibiotics is discussed in more detail in Chapter 37.

Protocols for prevention of infection with GBS in the newborn by administration of a penicillin to the mother were published in 1992 by ACOG [632] and the American Academy of Pediatrics (AAP) [633]. These guidelines were revised in 1996 by the CDC [634]; in 1997 by the AAP [635]; and in 2002 by the CDC [636], AAP, and ACOG [484]. More recent data suggest that nearly 50% of women receive intrapartum chemoprophylaxis because of the presence of one or more risk factors for neonatal sepsis or because of a positive antenatal screening culture for GBS [637].

When ampicillin or penicillin is administered to the mother, drug concentrations in the fetus are more than 30% of the concentrations in the blood of the mother [638]. Concentrations of penicillin, ampicillin, and cefazolin that are bactericidal for GBS are achieved in the amniotic fluid approximately 3 hours after completion of a maternal intravenous dose. Parenteral antibiotic therapy administered to a mother with signs of chorioamnionitis in labor essentially is treating the fetus early in the course of the intrapartum infection [639,640]. For some infected fetuses, the treatment administered in utero is insufficient, however, to prevent signs of early-onset group B streptococcal disease. Although maternal intrapartum prophylaxis has been associated with a 75% decrease in the incidence of early-onset group B streptococcal disease since 1993 [641,642], the regimen has had no impact on the incidence of late-onset disease [643].

The various algorithms prepared to guide empirical management of the neonate born to a mother with risk factors for group B streptococcal disease who received intrapartum antimicrobial prophylaxis for prevention of early-onset group B streptococcal disease focus on three clinical scenarios [641–644]:

1. Infants who have signs of sepsis should receive a full diagnostic evaluation and should be treated, typically with ampicillin and gentamicin, until laboratory studies are available.
2. Infants born at 35 or more weeks' gestation who appear healthy and whose mothers received intrapartum prophylaxis with penicillin, ampicillin, or cefazolin for 4 or more hours before delivery do not have to be evaluated or treated, but should be observed in the hospital for 48 hours.
3. Infants who are less than 35 weeks' gestation who appear healthy and whose mothers received penicillin, ampicillin, or cefazolin for less than 4 hours before delivery should receive a limited evaluation, including a blood culture and a complete blood cell count with a differential count, and be observed for 48 hours in the hospital. The same management probably is necessary for infants of any gestation whose mothers received vancomycin for prophylaxis because nothing is known about the amniotic fluid penetration of this drug or its efficacy in preventing early-onset group B streptococcal disease.

The first two clinical scenarios are readily identified, but the third category often leads to controversy regarding optimal management. Recommendations for prevention and treatment of early-onset group B streptococcal infection are discussed in detail in Chapter 12.

Management of the infant born to a mother who received an antimicrobial agent within hours of delivery must include consideration of the effect of the drug on cultures obtained from the infant after birth. Intrapartum therapy provides some treatment of the infant in utero, and variable concentrations of drug are present in the infant's body fluids. If the infant is infected and the

bacterial pathogen is susceptible to the drug administered to the mother, cultures of the infant can be sterile despite a clinical course suggesting sepsis.

## TREATMENT OF AN INFANT WHOSE BACTERIAL CULTURE RESULTS ARE NEGATIVE

Whether or not the mother received antibiotics before delivery, the physician must decide on the subsequent course of therapy for the infant who was treated for presumed sepsis and whose bacterial culture results are negative. If the neonate seems to be well and there is reason to believe that infection was unlikely, treatment can be discontinued at 48 hours. If the clinical condition of the infant remains uncertain and suspicion of an infectious process remains, therapy should be continued as outlined for documented bacterial sepsis unless another diagnosis becomes apparent. Significant bacterial infection can occur without bacteremia. Squire and colleagues [645] found that results of premortem blood cultures were negative in 7 (18%) of 39 infants with unequivocal infection at autopsy. Some infants with significant systemic bacterial infection may not be identified by the usual single blood culture technique. The physician must consider this limitation when determining length of empirical therapy. If treatment for infection is deemed necessary, parenteral administration for 10 days is recommended.

## MANAGEMENT OF AN INFANT WITH CATHETER-ASSOCIATED INFECTION

Investigators in Connecticut found that multiple catheters, low birth weight, low gestational age at birth, and low Apgar scores were significant risk factors for late-onset sepsis [504]. Benjamin and colleagues [505] reported a retrospective study at Duke University from 1995-1999 of all neonates who had central venous access. The goal of the Duke study was to evaluate the relationship between central venous catheter removal and outcome in bacteremic neonates. Infants bacteremic with *S. aureus* or a gram-negative rod who had their catheter retained beyond 24 hours had a 10-fold higher rate of infection-related complications than infants in whom the central catheter was removed promptly. Compared with neonates who had three or fewer positive intravascular catheter blood cultures for CoNS, neonates who had four consecutive positive blood cultures were at significantly increased risk for end-organ damage and death. In neonates with infection associated with a central venous catheter, prompt removal of the device is advised, unless there is rapid clinical improvement and sterilization of blood cultures after initiation of therapy.

## TREATMENT OF NEONATAL MENINGITIS

Because the pathogens responsible for neonatal meningitis are largely the same as the pathogens that cause neonatal sepsis, initial therapy and subsequent therapy are similar. Meningitis caused by gram-negative enteric bacilli can pose special management problems. Eradication of the pathogen often is delayed, and serious complications can occur [23,119,348,632]. The persistence of gram-negative bacilli in CSF despite bactericidal levels of the antimicrobial agent led to the evaluation of lumbar intrathecal [646] and intraventricular [647] gentamicin. Mortality and morbidity were not significantly different in infants who received parenteral drug alone or parenteral plus intrathecal therapy [646]. The study of intraventricular gentamicin was stopped early because of the high mortality in the parenteral plus intraventricular therapy group [647].

Feigin and colleagues [629] reviewed the management of meningitis in children, including neonates. Ampicillin and penicillin G, initially with an aminoglycoside, are appropriate antimicrobial agents for treating infection caused by GBS. Cefotaxime has excellent in vitro and in vivo bactericidal activity against many microorganisms responsible for neonatal meningitis [621]. Treatment of enteric gram-negative bacillary meningitis should include cefotaxime and an aminoglycoside until results of susceptibility testing are known.

If meningitis develops in a low birth weight infant who has been in the nursery for a prolonged period or in a neonate who has received previous courses of antimicrobial therapy for presumed sepsis, alternative empirical antibiotic regimens should be considered. Enterococci and antibiotic-resistant gram-negative enteric bacilli are potential pathogens in these settings. A combination of vancomycin, an aminoglycoside, and cefotaxime may be appropriate. Ceftazidime or meropenem in addition to an aminoglycoside should be considered for *P. aeruginosa* meningitis.

Other antibiotics may be necessary to treat highly resistant organisms. Meropenem [648], ciprofloxacin [649–651], or trimethoprim-sulfamethoxazole [652,653] can be the only antimicrobial agents active in vitro against bacteria that are highly resistant to broad-spectrum β-lactam antibiotics or aminoglycosides. Some of these drugs require careful monitoring because of toxicity to the newborn (see Chapter 37), and ciprofloxacin has not been approved for use in the United States in infants. Definitive treatment of meningitis caused by gram-negative enteric bacilli should be determined by in vitro susceptibility tests; consultation with an infectious diseases specialist can be helpful.

Use of dexamethasone as adjunctive treatment in childhood bacterial meningitis has been recommended based on reduction of neurologic sequelae in infants and children, in particular hearing loss and especially in cases of *H. influenzae* type b meningitis. Only one randomized controlled study exists for neonates; in 52 full-term neonates, mortality (22% dexamethasone versus 28% controls) and morbidity at 24 months (30% versus 39%) were not significantly different between groups [654]. If cultures of blood and CSF for bacterial pathogens by usual laboratory techniques are negative in the neonate with meningitis, the differential diagnosis of aseptic meningitis must be reviewed, particularly in view of diagnosing treatable infections (Table 6–18).

## MANAGEMENT OF AN INFANT WITH A BRAIN ABSCESS

If purulent foci or abscesses are present, they should be drained. Some brain abscesses resolve with medical therapy alone, however [348,655]. Brain abscesses can be

**TABLE 6–18** Infectious and Noninfectious Causes of Aseptic Meningitis* in Neonates

| Cause | Disease |
|---|---|
| ***Infectious Agent*** | |

**Aseptic meningitis is defined as meningitis in the absence of evidence of a bacterial pathogen detectable in cerebrospinal fluid by usual laboratory techniques.*

polymicrobial or result from organisms that uncommonly cause meningitis, such as *Citrobacter* [148,150], *Enterobacter* [130], *Proteus* [348], and *Salmonella* species [651]. Aspiration of the abscess provides identification of the pathogens to guide rational antimicrobial therapy.

## TREATMENT OF AN INFANT WITH MENINGITIS WHOSE BACTERIAL CULTURE RESULTS ARE NEGATIVE

In the absence of a detectable bacterial pathogen, an aggressive diagnostic approach is necessary for the infant with meningitis, defined by CSF pleocytosis and variable changes in the concentration of CSF protein and glucose. The most frequent cause of aseptic or nontuberculous bacterial meningitis in the neonate is prior antimicrobial therapy resulting in negative blood and CSF cultures. Congenital infections need to be excluded. Treatable diseases, such as partially treated bacterial disease and meningoencephalitis caused by herpes simplex virus, syphilis, cytomegalovirus, toxoplasmosis, Lyme disease in regions where *Borrelia* is prevalent, tuberculosis, and malignancy, need to be considered in the differential diagnosis. The history of illness and contacts in the mother and family members and epidemiologic features, such as animal exposures and recent travel, should be explored. Reexamination of the infant for focal signs of disease, including special techniques such as ophthalmologic examination, and appropriate diagnostic imaging studies of the long bones, skull, and brain can provide further information in determining the source of infection. Treatment of possible bacterial or nonbacterial causes of aseptic meningitis may be necessary before the results of culture, polymerase chain reaction, or serology tests are available to indicate the diagnosis.

## TREATMENT OF ANAEROBIC INFECTIONS

The importance of anaerobic bacteria as a cause of serious neonatal infection is uncertain. *Clostridium*, *Peptococcus*, and *Peptostreptococcus* are highly sensitive to penicillin G, but *B. fragilis* usually is resistant. If anaerobic organisms are known or suspected to be responsible for infection (as in peritonitis), initiating therapy with a clinically appropriate agent, such as clindamycin, metronidazole, meropenem, ticarcillin, or piperacillin/tazobactam, is warranted.

## ADJUNCTIVE THERAPIES FOR TREATMENT OF NEONATAL SEPSIS

Despite appropriate antimicrobial and optimal supportive therapy, mortality rates resulting from neonatal sepsis remain high, especially for infants with very low birth weight. With the hope of improving survival and decreasing the severity of sequelae in survivors, investigators have considered adjunctive modes of treatment, including granulocyte transfusion, exchange transfusion, and the use of standard intravenous immunoglobulin (IVIG) or pathogen-specific polyclonal or monoclonal antibody reagents for deficits in neonatal host defenses. These therapies are discussed in further detail in Chapter 4. Pentoxifylline has been documented to reduce plasma tumor necrosis factor-$\alpha$ concentrations in premature infants with sepsis and to improve survival, but the number of infants treated (five of five survived) and number of controls (one of four survived) were too small to provide more than a suggestion of efficacy [656]. In neutropenic infants with sepsis, the administration of granulocyte colony-stimulating factor and human granulocyte-macrophage colony-stimulating factor has had variable effects on outcome [657–660]. Although the results of selected studies indicate that some of these techniques improved survival, the potential adverse effects (e.g., graft-versus-host reaction, pulmonary leukocyte sequestration) are sufficiently concerning to warrant further study in experimental protocols.

IVIG preparations have been assessed for adjunctive therapy for neonatal sepsis based on the hypothesis that infected infants lack circulating antibodies against bacterial pathogens and that IVIG can provide some antibody for protection. Ohlsson and Lacy [661] performed a meta-analysis of 553 neonates with suspected infection who had been enrolled in randomized clinical trials in seven countries through 2003 to evaluate the effect of

IVIG on subsequent outcomes. The results revealed a borderline significant reduction in mortality (relative risk 0.63, 95% confidence interval 0.40 to 1.00). In the studies in which analysis was restricted to neonates with subsequently proven systemic bacterial infection, a statistically significant reduction of mortality was identified (relative risk 0.55, 95% confidence interval 0.31 to 0.98). Based on these preliminary encouraging data from diverse studies, an ongoing, placebo-controlled multicenter trial in low birth weight or ventilated neonates (INIS [International Neonatal Immunotherapy Study]) is comparing the adjunctive use of 10 mg/kg of IVIG versus placebo at the time of suspected infection and 48 hours later; mortality and major disability at 2 years are the major outcome variables [662].

## PROGNOSIS

Before the advent of antibiotics, almost all infants with neonatal sepsis died [5]. Dunham [2] reported that physicians used various treatments, including "erysipelas serum" and transfusions, without altering the course of the disease. The introduction of sulfonamides and penicillin and later introduction of broad-spectrum antibiotics such as chloramphenicol and streptomycin decreased the mortality rate to about 60% [3,5]. During this period, some infants undoubtedly died because of treatment with high dosages of chloramphenicol, which can cause cardiovascular collapse (i.e., gray baby syndrome).

The introduction of the aminoglycosides, first with kanamycin in the early 1960s and gentamicin late in that decade, vastly improved therapy for bacteremia caused by gram-negative organisms, the leading cause of sepsis at that time [6]. These therapies, together with an improved understanding of neonatal physiology and advances in life-support systems, combined to result in a steady decrease in neonatal mortality in the United States [6] and in Europe [257,258,286,663] during the period 1960-1985. Mortality rates for sepsis, including infants of all weights and gestational ages, decreased from 40% to 50% in the 1960s [4,6,286,663] to 10% to 20% in the 1970s and 1980s [6,10,258,447,663]. Population-based surveillance of selected counties in the United States conducted by the CDC from 1993-1998 reported 2196 cases of neonatal sepsis caused by GBS, of which 92 (4%) were fatal [643].

The postnatal age at which infection occurs, previously thought to be of prognostic significance, has become less important within the past 2 decades. Fulminant sepsis, with signs of illness present at birth or during the first day of life, has a high mortality rate, ranging from 14% to 20% [6,12,258,288] to 70% [664]. When infections occurring during the first 24 hours of life, most of which are caused by GBS, are excluded from the analysis, however, the percentage of deaths resulting from early-onset sepsis does not differ significantly from late-onset infection.* Mortality from sepsis is higher for preterm than for term infants in virtually all published studies,† but is approximately the same for all major bacterial pathogens (see Tables 6–4 and 6–5) [10,257].

In more recent surveys, the mortality rate for neonatal meningitis has declined from 25% [10,24,665,666] to 10% to 15% [12,23,26,667,668]. This decrease represents a significant improvement from prior years, when studies reported a case-fatality rate of more than 30% [21,431,648,649,669]. Mortality is greater among preterm than term infants [12,23,26,670].

Significant sequelae develop in 17% to 60% of infants who survive neonatal meningitis caused by gram-negative enteric bacilli or GBS [23,665–668]. These sequelae include mental and motor disabilities, convulsive disorders, hydrocephalus, hearing loss, and abnormal speech patterns. The most extensive experience with the long-term observation of infants who had group B streptococcal meningitis as neonates was reported by Edwards and colleagues [670]. During the period 1974-1979, 61 patients were treated, and 21% died. Of the 38 survivors who were available for evaluation at 3 years of age or older, 29% had severe neurologic sequelae, 21% had minor deficits, and 50% were functioning normally. Presenting factors that were associated with death or severe disability included comatose or semicomatose state, decreased perfusion, total peripheral white blood cell count less than 5000/mm$^3$, absolute neutrophil count less than 1000/mm$^3$, and CSF protein level greater than 300 mg/dL.

Another study evaluating 35 newborns who survived GBS meningitis over 3 to 18 years showed more favorable outcomes with 60% of survivors considered normal at the time of follow-up compared with sibling controls, 15% with mild to moderate neurologic residua, and 25% with major sequelae [669]. Franco and coworkers [668] reported the results of frequent and extensive neurologic, developmental, and psychometric assessments on a cohort of 10 survivors of group B streptococcal meningitis followed for 1 to 14 years. The investigators found that one child had severe CNS damage; five children, including one with hydrocephalus, had mild academic or behavioral problems; and four children were normal.

The neurodevelopmental outcomes described for infants with gram-negative bacillary meningitis are similar to the outcomes reported for group B streptococcal meningitis. Unhanand and colleagues [23] reported findings from their 21-year experience with gram-negative meningitis at two hospitals in Dallas, Texas. Of 72 patients less than 28 days old at the onset of symptoms, there were 60 survivors, 43 of whom were followed and evaluated for at least 6 months. Neurologic sequelae, occurring alone or in combination, were described in 56% and included hydrocephalus (approximately 30%), seizure disorder (approximately 30%), developmental delay (approximately 30%), cerebral palsy (25%), and hearing loss (15%). At follow-up, 44% of the survivors were developmentally normal at follow-up. Among infants with gram-negative bacillary meningitis, thrombocytopenia, CSF white blood cell count greater than 2000/mm$^3$, CSF protein greater than 200 mg/dL, CSF glucose-to-blood glucose ratio of less than 0.5, prolonged (>48 hours) positive CSF cultures, and elevated endotoxin and interleukin-1 concentrations in CSF were indicators of a poor outcome

*References [6, 10, 85, 257, 258, 286, 447].

†References [7, 10, 12, 18, 257, 258, 446, 447].

[23,433,541,671]. Investigators in England and Wales [668] found that independent predictors of adverse outcome 12 hours after admission were the presence of seizures, coma, ventilatory support, and leukopenia.

CT reveals a high incidence of CNS residua among newborns with meningitis. McCracken and colleagues [672] reported that of CT scans performed in 44 infants with gram-negative bacillary meningitis, only 30% of the scans were considered normal. Hydrocephalus was found in 20% of cases; areas of infarct, cerebritis, diffuse encephalomalacia, or cortical atrophy were found in 30%; brain abscess was found in about 20%; and subdural effusions were found in 7%. Two or more abnormalities were detected in about one third of infants.

The prognosis of brain abscess in the neonate is guarded because about half of these children die, and sequelae such as hydrocephalus are common among survivors. Of 17 children who had brain abscess during the neonatal period and were followed for at least 2 years, only 4 had normal intellect and were free of seizures [348]. In neonates with brain abscess, the poor outcome probably is caused by destruction of brain parenchyma as a result of hemorrhagic infarcts and necrosis.

# PREVENTION

## OBSTETRIC FACTORS

Improvement in the health of pregnant women with increased use of prenatal care facilities has led to lower rates of prematurity. Increased use of antenatal steroids in pregnant women with preterm labor and of surfactant in their infants has resulted in significantly fewer cases of respiratory distress syndrome. More appropriate management of prolonged interval after rupture of maternal membranes, maternal peripartum infections, and fetal distress has improved infant outcomes. Because these factors are associated with sepsis in the newborn, improved care of the mother should decrease the incidence of neonatal infection. The development of neonatal intensive care expertise and units with appropriate equipment has resulted in the survival of very low birth weight infants. Increasingly, obstetric problems are anticipated, and mothers are transferred to medical centers with NICUs before delivery.

## CHEMOPROPHYLAXIS

The use of antibiotics to prevent infection can be valuable when they are directed against specific microorganisms for a limited time. In the neonate, the use of silver nitrate eye drops or intramuscular ceftriaxone to prevent gonococcal ophthalmia, vaccination with bacillus Calmette-Guérin or prophylactic use of isoniazid to reduce morbidity from tuberculosis in infants who must return to endemic areas, and use of hexachlorophene baths to prevent staphylococcal disease have been recognized as effective modes of chemoprophylaxis. The value of using antimicrobial agents against unknown pathogens in infants believed to be at high risk of infection or undergoing invasive procedures is uncertain. Studies of penicillin administered to the mother during labor for prevention of neonatal disease caused by GBS are reviewed earlier and in Chapter 12.

Prophylaxis using low-dose vancomycin as a strategy to prevent late-onset sepsis in high-risk neonates has been the subject of several more clinical investigations [673–676]. A meta-analysis incorporating these studies found that low-dose prophylactic vancomycin reduced the incidence of total neonatal nosocomial sepsis and specifically CoNS sepsis in preterm infants, but that mortality and length of NICU stay did not differ between the treatment and placebo groups [677]. A potential confounding factor in these studies is that low-dose vancomycin in the intravenous infusion may itself have prevented recovery of pathogens from blood cultures drawn from the central lines. Because clear clinical benefits have not been shown, the rationale for routine prophylaxis with intravenous vancomycin cannot presently outweigh the theoretical concern of selection for antibiotic-resistant pathogens (e.g., vancomycin-resistant enterococci).

An intriguing alternative approach was studied in a randomized prospective trial by Garland and colleagues [678]—the use of a vancomycin-heparin lock solution in peripherally inserted central catheters in neonates with very low birth weight and other critically ill neonates. The study found the antibiotic lock solution to be associated with a marked reduction in the incidence of catheter-associated bloodstream infections (5% versus 30% in controls), providing proof-of-principle for wider investigation of this method that reduces systemic antibiotic exposure [678].

## MATERNAL FACTORS

The antiviral and antibacterial activity of human milk has been recognized for many years [679–682] and is discussed extensively in Chapter 5. Evidence that breast-feeding defends against neonatal sepsis and gram-negative meningitis was first reported more than 30 years ago from Sweden [683]. Studies done in Pakistan have shown that even partial breast-feeding seems to be protective among neonates in a resource-limited nation with a high neonatal mortality rate from clinical sepsis [684]. In a study from Georgetown University, very low birth weight infants fed human milk had a significant reduction in sepsis or meningitis compared with very low birth weight infants exclusively fed formula (odds ratio 0.47, 95% confidence interval 0.23 to 0.95) [685].

Breast-fed infants have a lower incidence of gastroenteritis, respiratory illness, and otitis media than formula-fed infants. A protective effect of breast-feeding against infections of the urinary tract also has been suggested [686]. Breast-feeding is also associated with general immunostimulatory effects as evidenced by larger thymus size [687] and improved antibody responses to immunization [688,689]. Lactoferrin is the major whey protein in human milk and has immunomodulatory activities A study of bovine lactoferrin supplementation in very low birth weight neonates identified efficacy in decreasing the incidence of late-onset sepsis. The decrease occurred for gram-positive bacteremia and fungemia [372].

## IMMUNOPROPHYLAXIS

The immaturity of the neonatal immune system is characterized by decreased levels of antibody against common pathogens; decreased complement activity, especially

alternative pathway components; diminished polymorphonuclear leukocyte production, mobilization, and function; diminished T-lymphocyte cytokine production to many antigens; and reduced levels of lactoferrin and transferrin [686]. Recognition of these factors has resulted in attempts at therapeutic intervention aimed specifically at each component of the deficient immune response [690].

Infants are protected from infection by passively transferred maternal IgG. To enhance the infant's ability to ward off severe infections, immunization of pregnant women and women in their childbearing years has been selectively adopted [688,691–693]. Programs in countries with limited resources to immunize pregnant women with tetanus toxoid have markedly decreased the incidence of neonatal tetanus. Investigational programs for immunization of pregnant women with polysaccharide pneumococcal, *H. influenzae* type b, and group B streptococcal vaccines aim to provide infants with protection in the first months of life. Studies of safety and immunogenicity of polysaccharide conjugate vaccines for GBS show promise of a reduction in incidence of late-onset and early-onset disease in newborns [693]. Use of vaccines in pregnant women is discussed in Chapter 38.

Several clinical trials have explored the use of IVIG to correct the antibody deficiency of neonates, particularly very preterm newborns, and reduce the incidence of sepsis. In 1994, the NICHD Neonatal Research Network reported a randomized clinical trial of 2416 subjects to determine the effects of prophylactic IVIG on the risk of sepsis in premature neonates [694]. No reduction in mortality, morbidity, or incidence of nosocomial infections was achieved by IVIG administration. The use of hyperimmune IVIG preparations and human monoclonal antibodies to prevent specific infections (e.g., CoNS, *S. aureus*) in high-risk neonates is also an area of active exploration; however, although these products seem to be safe and well tolerated, no reduction in staphylococcal infection was documented in two more recent large, randomized multicenter studies [695,696]. A systematic meta-analysis of 19 published studies through 2003 including approximately 5000 infants calculated that IVIG prophylaxis provided a 3% to 4% reduction in nosocomial infections, but did not reduce mortality or other important clinical outcomes (e.g., necrotizing enterocolitis, length of hospital stay) [697]. The costs of IVIG and the value assigned to these clinical outcomes are expected to dictate use; basic scientists and clinicians need to explore new avenues for prophylaxis against bacterial infection in this special patient population [697].

An older study by Sidiropoulos and coworkers [698] explored the potential benefit of low-dose (12 g in 12 hours) or high-dose (24 g daily for 5 days) IVIG given to pregnant women at risk for preterm delivery because of chorioamnionitis. Cord blood IgG levels were doubled in infants older than 32 weeks' gestational age whose mothers received the higher dosage schedule, but were unaffected in infants born earlier, suggesting little or no placental transfer of IVIG before the 32nd week of gestation. Among the infants delivered after 32 weeks, 6 (37%) of 16 born to untreated mothers developed clinical, laboratory, or radiologic evidence of infection and required antimicrobial therapy, whereas none of 7 infants born to treated mothers became infected. Although this study suggests that intrauterine fetal prophylaxis can be beneficial in selected cases, widespread use of IVIG for all women having premature onset of labor is not feasible because of uncertain timing before delivery, widespread shortages of IVIG, and cost.

The decreased number of circulating polymorphonuclear leukocytes and reduced myeloid reserves in the bone marrow of newborns have been ascribed to impaired production of cytokines, interleukin-3, granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, tumor necrosis factor-$\alpha$, and interferon-$\gamma$ [699,700]. Considerable experience with in vitro myeloid cell cultures and animal models [701,702] suggested that cytokine or growth factor therapy to stimulate myelopoiesis could be an effective aid in preventing sepsis among newborns with hereditary or acquired congenital neutropenia. Individual studies of prophylactic granulocyte-macrophage colony-stimulating factor in neonates were inconsistent in showing that absolute neutrophil counts are increased or that the incidence of sepsis is reduced [659,660,703]. A single-blind, multicenter randomly controlled trial of granulocyte-macrophage colony-stimulating factor in 280 infants at 31 weeks' gestation or less showed that although neutrophil counts increased more rapidly in the treatment group in the first 11 days after study initiation, there were no differences in the incidence of sepsis or improved survival associated with these changes [704]. Although therapy of severe congenital neutropenia with granulocyte colony-stimulating factor reverses neutropenia, demonstrable functional deficiency of the neutrophils persists, and this probably explains why these neonates remain at significantly elevated risk of infection [705].

The amino acid glutamine has been recognized as important for gut and immune function in critically ill adults, and more recent attention has focused on its potential benefit to neonates, especially because it is not included in standard intravenous amino acid solutions. A large, multicenter double-blind clinical trial of glutamine supplementation was found not to decrease the incidence of sepsis or the mortality in extremely low birth weight infants [706], and this failure to provide a statistically significant benefit was borne out in a meta-analysis of seven randomized trials including more than 2300 infants [707].

A few studies have examined the effect of probiotic administration of *Lactobacillus* or *Bifidobacterium* species, generally intended as prophylaxis against necrotizing enterocolitis in neonates, on the secondary outcome of systemic bacterial infection, yielding conflicting results [708–710]. A meta-analysis of nine randomized trials comprising 1425 infants suggested that enteral supplementation of probiotic bacteria reduced the risk of severe necrotizing enterocolitis, but there was no evidence of a comparable beneficial effect on the incidence of nosocomial sepsis [711].

The iron-binding glycoprotein lactoferrin is a component of the innate immune system produced at mucosal sites and activated in response to infection or inflammation. By restricting microbial iron access and through the direct cell wall lytic activity of its component peptides, lactoferrin exhibits broad-spectrum antimicrobial activity

[712]. Bovine lactoferrin, sharing 77% homology with the human protein, has been granted "generally recognized as safe" (GRAS) status by the FDA. A randomized study of bovine lactoferrin supplementation in very low birth weight neonates showed a reduced rate of a first episode of late-onset sepsis in the treatment group (risk ratio 0.34, 95% confidence interval 0.17 to 0.70) [372]. This simple, promising intervention warrants further exploration as a tool to reduce the incidence of nosocomial infection in this extremely high-risk population.

## DECONTAMINATION OF FOMITES

Because contamination of equipment poses a significant infectious challenge for the newborn, disinfection of all materials that are involved in the care of the newborn is an important responsibility of nursery personnel. The basic mechanisms of large pieces of equipment must be cleaned appropriately or replaced because they have been implicated in nursery epidemics. The use of disposable equipment and materials packaged in individual units, such as containers of sterile water for a nebulization apparatus, are important advances in the prevention of infection. The frequency of catheter-associated CoNS sepsis has led to attempts to prevent bacterial colonization of intravascular catheters through use of attachment-resistant polymeric materials, antibiotic impregnation, and immunotherapy directed against adherence factors [713]. These procedures are reviewed in Chapter 35.

## EPIDEMIOLOGIC SURVEILLANCE

### Endemic Infection

Nursery-acquired infections can become apparent days to several months after discharge of the infant. A surveillance system that provides information about infections within the nursery and involves follow-up of infants after discharge should be established. Various techniques can be used for surveillance and are reviewed in Chapter 35.

### Epidemic Infection

The medical and nursing staff must be aware of the possibility of outbreaks or epidemics in the nursery. Prevention of disease is based on the level of awareness of personnel. Infection in previously well infants who lack high-risk factors associated with sepsis must be viewed with suspicion. Several cases of infection occurring within a brief period caused by the same or an unusual pathogen and occurring in close physical proximity should raise concern about the possibility of a nursery outbreak. Techniques for management of infection outbreaks in nurseries are discussed in Chapter 35.

# SEPSIS IN THE NEWBORN RECENTLY DISCHARGED FROM THE HOSPITAL

When fever or other signs of systemic infection occur in the first weeks after the newborn is discharged from the nursery, appropriate management requires consideration of the possible sources of infection. Infection acquired at birth or from a household contact is the most likely cause. Congenital infection can be present with signs of disease that are detected after discharge. Late-onset infection from microorganisms acquired in the nursery can occur weeks or occasionally months after birth. Infection can occur after discharge because of underlying anatomic, physiologic, or metabolic abnormalities.

Newborns are susceptible to infectious agents that colonize or cause disease in other household members. If an infant whose gestation and delivery were uneventful is discharged from the nursery and develops signs of an infectious disease in the first weeks of life, the infection was probably acquired from someone in the infant's environment. Respiratory and gastrointestinal infections are common and can be accompanied by focal disease such as otitis media. A careful history of illnesses in household members can suggest the source of the infant's infection.

## CONGENITAL INFECTION

Signs of congenital infection can appear or be identified after discharge from the nursery. Hearing impairment caused by congenital rubella or cytomegalovirus infection can be noticed by a parent at home. Hydrocephalus with gradually increasing head circumference caused by congenital toxoplasmosis is apparent only after serial physical examinations. Chorioretinitis, jaundice, or pneumonia can occur as late manifestations of congenital infection. A lumbar puncture may be performed in the course of a sepsis evaluation. CSF pleocytosis and increased protein concentration can be caused by congenital infection and warrant appropriate follow-up diagnostic studies.

## LATE-ONSET INFECTION

Late-onset infection can manifest after the first week to months after birth as sepsis and meningitis or other focal infections. GBS (see Chapter 12) is the most frequent cause of late-onset sepsis in the neonate, followed by *E. coli*. Organisms acquired in the nursery also can cause late-onset disease. Skin and soft tissue lesions or other focal infections, including osteomyelitis and pneumonia from *S. aureus*, can occur weeks after birth. The pathogenesis of late-onset sepsis is obscure in many cases. The reason why an organism becomes invasive and causes sepsis or meningitis after colonizing the mucous membranes; skin; or upper respiratory, genitourinary, or gastrointestinal tracts remains obscure. Nosocomially acquired or health care–associated organisms are discussed in further detail in Chapter 35.

## INFECTIONS IN THE HOUSEHOLD

Infection can be associated with an underlying anatomic defect, physiologic abnormality, or metabolic disease. An infant who fails to thrive or presents with fever can have a urinary tract infection as the first indication of an anatomic abnormality. Infants with lacrimal duct stenosis or choanal atresia can develop focal infection. Sepsis caused by gram-negative enteric bacilli occurs frequently in infants with galactosemia (see "Pathogenesis").

The infected infant can be an important source of infection to family members. In one study in New York [714], 12.6% of household contacts developed suppurative lesions during the 10-month period after introduction into the home of an infant with a staphylococcal lesion. The incidence of suppurative infections in household contacts of infants without lesions was less than 2%. Damato and coworkers [713] showed colonization of neonates with enteric organisms possessing R factor–mediated resistance to kanamycin and persistence of these strains for more than 12 months after birth. During the period of observation, one third of the household contacts of the infants became colonized with the same strain.

Infections in infants have been associated with bites or licks from household pets. *Pasteurella multocida* is part of the oral flora of dogs, cats, and rodents. A review of 25 cases of *P. multocida* infection in the neonatal period found animal exposure to cats or dogs or both in 52% of cases, most of which did not involve bites or trauma; the balance were believed to represent vertical transmission from an infected mother [715]. In one case report, a 5-week-old infant with *P. multocida* meningitis frequently was licked by the family dog, and the organism was identified in cultures of the dog's mouth, but not of the parents' throats [716]. *P. multocida* sepsis and meningitis was reported in 2-month-old twin infants after household exposure to a slaughtered sheep [717]. A neonatal case of *Campylobacter jejuni* sepsis was proven genetically to result from transmission from the family dog [718]. The epidemiologic link between cats and dogs and infection in young infants suggests that parents should limit contact between pets and infants.

## FEVER IN THE FIRST MONTH OF LIFE

Reviews of fever in the first weeks of life indicate that elevation of temperature (>38.8° C [>101.8° F]) [719–724] is relatively uncommon. When fever occurs in the young infant, the incidence of severe disease, including bacterial sepsis, meningitis, and pneumonia, is sufficiently high to warrant careful evaluation and conservative management [719,725]. Approximately 12% of all febrile (>38° C [>100.4° F]) neonates presenting to emergency departments are found to have a serious bacterial infection [726,727]. Important pathogens in neonatal age groups include *GBS* and *E. coli*, and occult bacteremia and urinary tract infections are the most common foci of disease [726,727].

A careful history of the pregnancy, delivery, nursery experience, interval since discharge from the nursery, and infections in the household should be obtained. Physical examination should establish the presence or absence of signs associated with congenital infection and late-onset diseases. Culture of blood and urine should be done if no other focus is apparent, and culture of CSF and a chest radiograph should be considered if the infant is believed to have systemic infection. Risk stratification algorithms have been evaluated to incorporate ancillary clinical testing in hopes of supplementing the often incomplete picture that emerges from history and physical examination [725].

The "Rochester criteria" for analysis of febrile infants, originally proposed by Dagan and colleagues [722], used criteria such as normal peripheral leukocyte count (5000 to 15,000/mm$^3$), normal absolute band neutrophil count (<1500/mm$^3$) and absence of pyuria to identify low-risk patients. When Ferrera and coworkers [721] retrospectively applied these criteria to the subset of patients in their first 4 weeks of life, 6% of the neonates fulfilling low-risk criteria had serious bacterial infections. Similarly, when groups of febrile newborns were retrospectively stratified as low risk by the "Philadelphia criteria" [728] or "Boston criteria" [729] developed for older infants, it became apparent that 3.5% to 4.6% of the neonates with a serious bacterial infection would have been missed [726,727].

Consequently, because of the inability to predict serious bacterial infections accurately in this age group, a complete sepsis evaluation should be performed and includes a culture of blood, urine, and CSF; a complete blood cell and differential count; examination of CSF for cells, glucose, and protein; and a urinalysis. Although a peripheral blood cell count is routinely ordered, it is not sufficiently discriminatory to preclude the mandatory collection of blood for culture [730,731]. In contrast to older infants [732], the presence of signs consistent with a viral upper respiratory tract infection in the neonate does not obviate the need for a full diagnostic evaluation. Neonates infected with respiratory syncytial virus had equivalent rates of serious bacterial infection as neonates testing negative for the virus [733]. More recent data suggest, however, that febrile infants less than 60 days of age positive for influenza virus infection may have lower rates of bacteremia and urinary tract infection than similar infants without influenza infection [734]. Because of the high rates of serious bacterial infections, guidelines prepared by Baraff and colleagues [719] for the management of infants and children with fever without source state that all febrile infants younger than 28 days should be hospitalized for parenteral antibiotic therapy, regardless of the results of laboratory studies.

## ACKNOWLEDGMENTS

Drs. S. Michael Marcy, Carol Baker, and Debra L Palazzi contributed to this chapter in earlier editions. The authors are indebted to these scholars for their roles in the preparation of this chapter.

CHAPTER 7

# Bacterial Infections of the Respiratory Tract

Elizabeth D. Barnett ✪ Jerome O. Klein

CHAPTER OUTLINE

## INFECTIONS OF THE ORAL CAVITY AND NASOPHARYNX

### PHARYNGITIS, RETROPHARYNGEAL CELLULITIS, AND RETROPHARYNGEAL ABSCESS

Neonates with bacterial infection of the oropharynx may present with pharyngeal inflammation with or without exudate or with retropharyngeal cellulitis or abscess. Clinical signs and symptoms include respiratory distress, poor feeding, and irritability. Infants may have submandibular swelling, and some may have a weak or hoarse cry. Infection may extend to the surrounding structures, leading to formation of deep neck abscess. Microorganisms identified as the etiologic agents of these infections and their manifestations of disease include the following:

*Staphylococcus aureus*. Although many children are colonized in the throat and nasopharynx with *S. aureus*, this organism is rarely a primary agent in the etiology of pharyngitis in infants (or adults). There have been reports, however, of localized abscesses in the oral cavity related to *S. aureus*. In 1936, Clark and Barysh [1] reported a case of retropharyngeal abscess in a 6-week-old infant. The infant was critically ill, but recovered after incision and drainage of the abscess. A 6-day-old infant described in a report from India presented with stridor, dysphagia, and lateral cervical swelling. The infant was found to have a retropharyngeal abscess caused by *S. aureus* [2]. Steinhauer [3] reported a case of cellulitis of the floor of the mouth (Ludwig angina) in a 12-day-old infant. The infant was febrile and toxic; examination of the mouth revealed swelling under the tongue. Purulent material was subsequently drained from this lesion, and *S. aureus* was isolated from the pus. A laceration was noted in the floor of the mouth, and the author considered this wound to be the portal of entry of the infection. Increased incidence of methicillin-resistant *S. aureus* has been reflected in two reports of retropharyngeal abscesses caused by methicillin-resistant *S. aureus* in infants 2 to 3 months of age. One case report involved a 2-month-old infant in Japan (who also had evidence of penicillin-resistant pneumococcus) [4], and the second case report involved 3- and 4-month-old infants in the United States, one of whom had extension of the abscess into the mediastinum accompanied by venous thrombosis [5].

*Streptococcus pyogenes*. Fever and pharyngeal inflammation may result from infection with *S. pyogenes* in the neonate [6].

*Streptococcus agalactiae*. Retropharyngeal cellulitis has been associated with bacteremia caused by group B streptococci (GBS) [7–9]. Affected neonates presented with poor feeding, noisy breathing, persistent crying, irritability, and widening of the retropharyngeal space on radiographs of the lateral neck. Stridor also may be associated with retropharyngeal abscess, as reported in a 13-day-old infant in Hong Kong [10]. A retropharyngeal abscess caused by GBS occurred in one of three neonates reported in a series of 31 cases of retropharyngeal abscess in children in Camperdown, Australia, during 1954-1990 [11,12]. This infant was found to have a third branchial arch pouch that was subject to recurrent infection until age 5 years.

*Listeria monocytogenes*. Small focal granulomas on the mucous membrane of the posterior pharynx have been observed in neonates with *L. monocytogenes* infection.

DOI: 10.1016/B978-1-4160-6400-8.00007-9

Necrosis of some of the granulomas results in ulcers on the pharynx and tonsils.

*Treponema pallidum*. Mucous patches occur on the lips, tongue, and palate of infants with congenital *T. pallidum* infection. Rhinitis may appear after the first week of life.

*Neisseria gonorrhoeae*. A yellow mucoid exudate of the pharynx may be present simultaneously with ophthalmia with *N. gonorrhoeae* infection (Yu A, personal communication, 1981). A case report of in utero gonococcal infection with involvement of multiple tissues included pharyngeal abscess [13].

*Enterococcus faecalis*. A case of retropharyngeal abscess in which culture of aspirated pus grew *E. faecalis* and two strains of coagulase-negative staphylococci occurred in a 2-week-old full-term infant from Australia [12]. The infant was severely ill and had atlantoaxial dislocation resulting in paraplegia. At autopsy, the findings included bacterial endocarditis, diffuse bilateral pneumonia, and renal infarcts.

*Escherichia coli*. *E. coli* can be a rare cause of infection of the pharyngeal cavity. Pus from a retropharyngeal abscess in a 1-week-old infant grew two strains of *E. coli* [12]. The infant was afebrile on presentation and had large midline pharyngeal swelling.

Infants may have coryza and other signs of upper respiratory tract disease secondary to infection with respiratory viruses. Infections with respiratory viruses may damage the respiratory mucosa, increasing susceptibility to bacterial infection of the respiratory tract. Eichenwald [14] described an apparent synergy of respiratory viruses and staphylococci that produced an upper respiratory tract infection called the “stuffy nose syndrome.” The syndrome occurred only when both organisms were present. Eichenwald and coworkers [15] also documented increased dissemination of bacteria by newborns carrying staphylococci and echovirus 20 or adenovirus type 2 in the nasopharynx and coined the term “cloud babies” for these infants. These studies have not been repeated by other investigators, and the significance of synergy of two or more microorganisms in neonatal respiratory infections is uncertain.

## NOMA

Noma (cancrum oris) is a destructive gangrenous process that may affect the nose, lips, and mouth. It occurs almost exclusively in malnourished children in developing countries; nutrient deficiencies have been postulated to play a role in its pathogenesis [16]. Although it is usually a chronic, destructive process in older children, in neonates it may be rapidly fatal. Affected neonates are usually premature and of low birth weight. In older children and adults, noma is caused by fusospirochetes such as *Fusobacterium necrophorum* [17]. The disease in neonates is usually due to *Pseudomonas aeruginosa*. Ghosal and coworkers [18] reported bacteriologic and histologic findings in 35 cases of noma in neonates in Calcutta. *P. aeruginosa* was isolated from blood or the gangrenous area in more than 90% of the cases. In Israel, a full-term infant with bilateral choanal atresia who required an airway developed gangrenous lesions of the cheek on day 11 and palatal lesions that progressed to ulceration and development of an oronasal fistula. Cultures of material from the lesions grew *P. aeruginosa* [19]. Freeman and associates [20] reported the development of noma neonatorum in the 3rd week of life in a 26-week-gestation premature infant; they suggested that this entity represents a neonatal form of ecthyma gangrenosum. Human immunodeficiency virus (HIV) testing has been recommended for infants in whom noma is diagnosed because of the difficulty distinguishing between the early signs of noma and necrotizing diseases of the oral cavity associated with HIV infection [21].

## EPIGLOTTITIS

Epiglottitis caused by *S. aureus* in an 8-day-old infant was reported by Baxter [22] in a survey of experience with the disease at Montreal Children’s Hospital from 1951-1965. Rosenfeld and associates [23] reported a second case of epiglottitis caused by *S. aureus* in a 5-day-old infant. The infant presented with bradycardia, hoarseness, and inspiratory stridor and had diffuse inflammation of the arytenoids and epiglottis. *S. aureus* was cultured from pus on the epiglottic surface; blood culture was negative. Epiglottitis secondary to *Streptococcus sanguis* in a newborn infant and secondary to GBS in an 11-week-old infant has also been reported [24,25].

## LARYNGITIS

Laryngitis in the newborn is rare. A newborn infant with congenital syphilis may have laryngitis and an aphonic cry. Hazard and coworkers [26] described a case of laryngitis caused by *Streptococcus pneumoniae*. A term infant was noted at 12 hours to have a hoarse cry, which progressed to aphonia during the next 3 days. Direct examination of the larynx revealed swelling and redness of the vocal cords. The infant was febrile (38.5° C), but the physical examination was unremarkable. *S. pneumoniae* was isolated from the amniotic fluid, the maternal cervix, and the larynx of the infant. The infant responded rapidly to treatment with parenteral penicillin G. More recently, laryngitis in infants has been linked with acid reflux [27]. Laryngitis may also be a sign of respiratory papillomatosis, usually associated with human papillomavirus.

## INFECTION OF THE PARANASAL SINUSES

The paranasal sinuses of the fetus begin to differentiate at about the 4th month of gestation. The sinuses develop by local evagination of nasal mucosa and concurrent resorption of overlying bone. The maxillary and ethmoid sinuses are developed at birth and may be sites for suppurative infection. The sphenoid and frontal sinuses are rudimentary at birth and are not well defined until about 6 years of age [28,29].

Inflammation may occur simultaneously in the paranasal sinuses, the middle ears, and the lungs. Autopsy may reveal that purulent exudate and leukocytic infiltration of the mucosa are present at one or more of these sites. Infection of the ethmoid and maxillary sinuses may be

severe and life-threatening in the newborn. Clinical manifestations include general signs of infection, such as fever, lethargy, irritability, and poor feeding, and focal signs indicative of sinus involvement (i.e., nasal congestion, purulent drainage from the nostrils, and periorbital redness and swelling). Proptosis may occur in severely affected children. Although any of the organisms responsible for neonatal sepsis may cause sinusitis, *S. aureus*, group A streptococci, and GBS are responsible for most infections [30–32]. Suppurative infection of the maxillary sinus may progress to osteomyelitis of the superior maxilla (see Chapter 8) [31].

Blood specimens, nasopharyngeal secretions, and purulent drainage material (if present) should be obtained for culture before treatment. Antibacterial therapy must include a penicillinase-resistant penicillin or cephalosporin for activity against *S. aureus*, group A streptococci, and GBS. If no material is available for examination of Gram-stained pus or if results of the preparation are ambiguous, initial therapy should include an aminoglycoside or a third-generation cephalosporin to ensure activity against gram-negative enteric bacilli (see discussion of management in Chapter 6). Surgical drainage of the infected site should be considered. Drainage of the suppurative maxillary sinus should be performed through the nose to avoid scars on the face and damage to the developing teeth [31].

## DIPHTHERIA

Neonatal diphtheria, although now extremely rare in the United States, was common before the development and extensive use of immunization with diphtheria toxoid. Outbreaks occurred in hospital nurseries. One of the most striking reports described three separate epidemics in a "foundling hospital" in Tipperary, Ireland, during 1937-1941; 36 infants younger than 1 month of age were affected, and 26 died [33]. Goebel and Stroder [34] described 109 infants younger than 1 year with diphtheria in Germany during the period from the fall of 1945 to the summer of 1947: 59 infants were younger than 1 month of age, and 26 died. In a report from the Communicable Disease Unit of the Los Angeles County Hospital covering a 10-year period ending June 1950, 1433 patients were admitted to the hospital with diphtheria; 19 patients were younger than 1 year, but only 2 patients were younger than 1 month of age [35]. Elsewhere, diphtheria also seems to be declining [35a]; only three cases of neonatal diphtheria were identified in India from 1974-1984 by Mathur and associates [36].

Respiratory diphtheria has been well controlled in the United States since the introduction of diphtheria toxoid in the 1920s, although it remained endemic in some states through the 1970s [37]. The results of a survey of cases of diphtheria reported to the Centers for Disease Control and Prevention (CDC) of the U.S. Public Health Service, Atlanta, Georgia, for the period 1971 to October 1975 showed that no cases involved children younger than 1 month of age and that only six cases occurred in children younger than 1 year (the youngest was 5 months old) (Filice G, personal communication, 1981). During the period 1980-1995, 41 cases of respiratory diphtheria were reported to the CDC; 4 (10%) were fatal, all of which occurred in unvaccinated children [38]. No cases of diphtheria have been reported in the United States since 2003 [38a]. Importation of diphtheria from countries where diphtheria remains endemic, or where a resurgence of disease occurred such as in the former Soviet Union, accounted for most of the cases in industrialized nations [39]. Reemergence of diphtheria in the newly independent states of the former Soviet Union underscored the need to maintain control measures in the United States, including universal childhood immunization, adult boosters, and maintenance of surveillance activities [40]. Maternal immunization may provide some protection to infants in the neonatal period before diphtheria vaccine is given [41].

A newborn receives antibodies to *Corynebacterium diphtheriae* from the mother if she is immune, and the titers of mother and infant at birth are approximately equivalent [42]. Some degree of protection results in the neonate from this passively transferred antibody. Serologic surveys performed in the United States in the 1970s and 1980s suggested that 20% to 60% of adults older than 20 years may be susceptible to diphtheria [43,44]. Additional data from Europe confirmed that many adults remain susceptible to diphtheria [45,46]. As is the case in general with passively transferred immunity, protection depends on the level of maternal antibody at the time of the infant's birth, and protection decreases during the months after birth unless the infant is immunized [47,48].

Neonatal diphtheria usually is localized to the nares. Diphtheria of the fauces is less common. The skin and mucous membranes may be affected; the two infants in Los Angeles included an 8-day-old neonate with diphtheritic conjunctivitis [35]. Because isolation of *C. diphtheriae* requires inoculation of special culture media, notification of the laboratory about the possibility of diphtheria is important. Specimens of nasal and pharyngeal secretions may improve yield of positive cultures [49]. Infants suspected to have diphtheria should be isolated and receive penicillin or erythromycin to eradicate the organism from the respiratory tract or other foci of infection to terminate toxin production and decrease likelihood of transmission. The mainstay of therapy is diphtheria antitoxin, which should be administered as soon as the diagnosis of diphtheria is considered. This product is available in the United States from the CDC [50].

## PERTUSSIS

Infants and young children in the United States are at the highest risk for pertussis and its complications [51]. Although the incidence of pertussis has declined markedly since 1934, when more than 250,000 cases were recorded, resurgence of disease since the early 1980s underscores the need for continued awareness of this disease [52]. There were 29,134 cases of pertussis in the United States in the years 1997-2000; 29% occurred in infants younger than 1 year, representing an 11% increase from surveillance data for 1994-1996 [53]. The number of deaths in infants younger than 4 months increased from 49 (64% of deaths from pertussis) in 1980-1989 to 84 (82% of deaths) in 1990-1999 [54]. In 2000, 17 deaths were attributed to pertussis in the United States; in all cases, onset of symptoms was before 4 months of age [55]. Hospitalization

rates for pertussis for infants did not change notably from 1993-2004 in the United States, with rates highest for infants 1 to 2 months of age (293 hospitalizations per 100,000 live births) [56].

Pertussis occurs in exposed and unprotected newborns [57]. From 1959-1977, pertussis was diagnosed in 400 children in Dallas hospitals; 69 patients (17%) were younger than 12 weeks of age. An adult in the household with undiagnosed mild disease was the usual source of infection for these neonates and young infants [58]. A report of a nursery outbreak in Cincinnati highlights the persistent threat of pertussis in young infants and in hospital personnel [59]. Between February and May 1974, pertussis developed in six newborns, eight physicians, and five nurses (documented by isolation of *Bordetella pertussis* from the nasopharynx). Four additional infants had clinical illness, but the organism was not isolated from the upper respiratory tract. Two mothers of uninfected infants became ill. The initial case was a 1-month-old infant managed in a ward whose infection spread to the nursery when house officers became infected and transmitted the organism to other newborns. A 2004 outbreak involved 11 infants exposed to an infected health care worker in a newborn nursery; the attack rate was 9.7%. The median age at diagnosis was 31 days; five infants required admission to the pediatric intensive care unit, four were treated in the general pediatric unit, one was treated in the emergency department, and one was treated as an outpatient [60].

In the United States in the early 1990s, cases of pertussis were reported from every state, and large outbreaks occurred in Cincinnati and Chicago [61]. In the Chicago outbreak, the highest attack rate was in infants younger than 6 months of age; factors associated with transmission of pertussis in this age group included young maternal age and cough lasting 7 days or longer in the mothers [62]. Another risk factor for pertussis may be low birth weight. A study of cases of pertussis in Wisconsin infants and young children concluded that children of low birth weight were more likely than their normal birth weight counterparts to contract pertussis and to be hospitalized with the disease [63]. Fatal pertussis was identified through a pediatric hospital–based active surveillance system in 16 infants in Canada from 1991-2001; 15 of 16 infants were 2 months of age or younger. When fatal cases were matched with 32 nonfatal cases by age, date, and geography, pneumonia and leukocytosis were identified as independent predictors of a fatal outcome in hospitalized infants [64]. A more recent report described the histopathologic findings in the respiratory tracts of 15 infants younger than 4 months of age who died of pertussis. The findings suggested that the organism triggers a cascade of events, including pulmonary vasoconstriction and release of pertussis toxins leading to increased leukocyte mass and refractory pulmonary hypertension [65].

Antibody to *B. pertussis* crosses the placenta, and titers in immune mothers and their newborns are approximately equal [42,43]. If high titers of the passively transferred antibody are present, the antibody is protective for the newborn; this was shown by Cohen and Scadron [66], who observed protection of 6 months' duration in the offspring of recently immunized women. Three cases of clinical pertussis occurred among six infants who were exposed to infection and whose mothers had not been immunized, whereas no cases occurred among eight similarly exposed infants of immunized mothers. In the group of infants 7 to 12 months old, there were two cases of clinical pertussis in offspring of immunized and unimmunized mothers, which suggests that passively transferred immunity was no longer present in the infants whose mothers had been immunized during pregnancy. Many women who were vaccinated during infancy have low levels of antibody when they reach childbearing age, and this concentration of antibody may be insufficient to protect offspring if the infants are exposed to pertussis during the first few months of life (before they are immunized). Older children and adults are important sources of infection for infants [67]. These findings suggest that maternal immunization would provide sufficient antibody to protect infants before durable immunity could be provided by infant immunization. In addition, adolescent and adult immunization could reduce the number of individuals able to contract pertussis and infect infants [68].

Clinical presentation of pertussis in newborns is similar to the presentation in older children, but may lack some features typical of disease in older children. The incubation period ranges from 5 to 10 days. The initial sign usually is mild coughing, which may progress over several days to severe paroxysms with regurgitation and vomiting of food. The characteristic "whoop" may be absent in infants. The clinical picture of the most severely affected infants may be dominated by marked respiratory distress, cyanosis, and apnea, rather than significant cough. Fever is usually absent. Lymphocyte counts are frequently greater than 30,000/mm$^3$. Cockayne [69] described a case of clinical pertussis in a neonate whose mother and brother were infectious at the time of birth. The infant began to cough on the 5th day of life and had a high white blood cell count (36,000/mm$^3$), with mostly lymphocytes. Phillips [70] reported two cases of pertussis in newborns who were infected by an obstetric nurse. The infants began to cough on the 8th and 10th days of life. Clinical signs of respiratory infection caused by *Chlamydia trachomatis* are similar to signs of pertussis (see Chapter 19).

Complications of pertussis in young infants include convulsions, bronchopneumonia, and hemorrhage. Bacterial and viral superinfection may occur. In a study of 182 infants and children younger than age 2 hospitalized with pertussis from 1967-1986 in Dallas, apnea and convulsions occurred significantly more frequently in infants younger than 3 months; the three deaths all were in 1-month-old infants with secondary bacterial infection [71]. Mortality among infants younger than 3 months is high; in the earlier Dallas series, 5 of 69 infants (7%) with onset of signs at 2 to 6 weeks died [50]. *B. pertussis* pneumonia may progress rapidly; pulmonary hypertension resulting from difficulty perfusing the congested lung may cause right-sided heart failure or fatal cardiac arrhythmias [72]. Long-term sequelae of whooping cough in infancy and early childhood were studied by Johnston and coworkers [73]; there was a significant reduction

in forced vital capacity in adulthood in individuals who had pertussis before age 7 compared with individuals who did not have pertussis. A case of hemolytic uremic syndrome in a neonate has been reported following pertussis [74].

Diagnostic methods for pertussis depend on the age of the patient and the duration of cough. In children younger than 11 years and older patients with cough lasting less than 14 days, nasopharyngeal specimens should be obtained for bacterial culture using Dacron or calcium alginate swabs. Best results are obtained if specimens are inoculated at the bedside or taken immediately to the laboratory in appropriate transport media. It is helpful to inform the laboratory of suspicion of pertussis because specialized agar (Regan-Lowe or Bordet-Gengou) is required. The organism is isolated most easily during the catarrhal or early paroxysmal stage of illness and rarely is found after the 4th week of illness. Direct fluorescent antibody testing of nasopharyngeal secretions has low sensitivity and variable specificity and cannot be relied on to diagnose pertussis. Polymerase chain reaction assay shows promise as a diagnostic tool [75,76], but no FDA-licensed test is available.

Serologic testing is the diagnostic method of choice for patients 11 years old or older in the absence of immunization within 2 years.

Antimicrobial therapy may lessen severity of the disease if it is given in the catarrhal stage, but it has no clinical effect after paroxysms occur. Antibiotic therapy eliminates carriage of organisms from the upper respiratory tract and is valuable in limiting communicability of infection, even if given late in the clinical course. Azithromycin, 10 mg/kg/day orally in one dose for 5 days, with a maximum daily dose of 600 mg, is the drug of choice for infants younger than one month of age [77]. An alternative is erythromycin estolate, 40 mg/kg/day orally in four divided doses for 14 days [77,78].

Resistance of *B. pertussis* to erythromycin has been reported [79], but does not seem to be widespread. Penicillins and first-generation and second-generation cephalosporins are ineffective against *B. pertussis*. One study showed clinical efficacy in treating pertussis with high-dose specific pertussis globulin from donors immunized with acellular pertussis vaccine [80], although efficacy of this regimen on a larger scale has not been proved. One investigator proposed a role for inhaled corticosteroids in the treatment of pertussis [81]. There are no data available to evaluate the role of albuterol or other β-adrenergic agents in the treatment of pertussis.

Erythromycin also is valuable in prevention of pertussis in exposed infants. Granstrom and colleagues [82] described use of erythromycin in 28 newborns of mothers with pertussis. The women had serologic or culture-confirmed pertussis at the time of labor. Mothers and their newborns received a 10-day course of erythromycin. The infected and treated mothers were allowed to nurse their infants. None of the infants developed signs or serologic evidence of pertussis. Erythromycin has also been shown to be effective in preventing secondary spread within households in which infants resided [83]. Azithromycin (10 mg/kg/day as a single dose for 5 days) is currently the preferred macrolide for prevention of pertussis in infants $< 1$ month of age, with erythromycin (40 mg/kg/day in 4 divided doses for 14 days) available as an alternative. Clarithromycin is not recommended in this age group. Chemoprophylaxis is also recommended for household and other close contacts, such as individuals in the hospital, including medical and surgical personnel [77,82,84].

Reports of clusters of cases of pyloric stenosis among infants given erythromycin for prophylaxis after exposure to pertussis have raised concern about using erythromycin in this setting [85,86]. A study of 469 infants given erythromycin during the first 3 months of life confirmed an association between systemic (but not ophthalmic) erythromycin and pyloric stenosis and identified that risk was highest in the first 2 weeks of life [87]. Because erythromycin is the only medication proven effective for this purpose and the only one approved for this use, and because pertussis can be life-threatening in the neonate, the drug remains one of the recommended agents, with azithromycin an alternative, until other regimens can be shown to be safe and effective. Health care professionals who prescribe erythromycin to newborns should inform parents of the risk of pyloric stenosis and counsel them about signs and symptoms of pyloric stenosis.

Two tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccines (Tdap) were licensed in 2005 to enhance protection against pertussis in adolescents and adults. Data are lacking at this time about safety of these vaccines administered during pregnancy or effectiveness in preventing disease in infants when administered to mothers. These vaccines are not currently recommended during pregnancy, but are recommended in the immediate postpartum period at an interval of at least 2 years from the last tetanus-diphtheria (Td) booster. If a Td booster is due during pregnancy, it is recommended that this be deferred in lieu of giving a dose of Tdap in the immediate postpartum period [88]. The U. S. Advisory Committee on Immunization Practices in 2006 recommended routine administration of Tdap for postpartum women (who were not vaccinated previously with Tdap) to provide personal protection and reduce the risk for transmitting *B. pertussis* to their infants [89]. The American Medical Association and American Academy of Pediatrics have advocated for immunization of parents and close contacts of newborns younger than 6 months of age for influenza and pertussis. These vaccines have also been recommended for health care workers who have direct patient contact [89].

## OTITIS MEDIA

Otitis media in the newborn may be an isolated infection, or it may be associated with sepsis, pneumonia, or meningitis. Acute otitis media is defined as the presence of fluid in the middle ear (middle ear effusion) accompanied by an acute sign of illness. Middle ear effusion may be present without other signs of acute illness. Diagnostic criteria for otitis media in newborns are the same as in older children,

but the vulnerability of the newborn and potential differences in the microbiology of otitis media in newborns, especially in the first 2 weeks of life, make it necessary to exercise special considerations in choosing antimicrobial therapy.

## PATHOGENESIS AND PATHOLOGY

During fetal life, amniotic fluid bathes the entire respiratory tree, including the lungs, paranasal sinuses, and middle ear cleft. Amniotic fluid and cellular debris usually are cleared from the middle ear in most infants within a few days after birth [90]. In term infants, the middle ear usually is well aerated, with normal middle ear pressure and normal tympanic membrane compliance, within the first 24 hours [91]. A study of 68 full-term infants examined by otoscopy, tympanometry, and acoustic reflectometry within the first 3 hours of life revealed the presence of middle ear effusion in all neonates; fluid was absent at 72 hours of life in almost all infants [92].

Studies of the middle ear at autopsy provide important information about the development of otitis media in the neonate. Inflammation in the lungs or paranasal sinuses usually was accompanied by inflammation in the middle ear [30,90–94]. deSa [90] examined 130 infants, including 36 stillborn infants, 74 neonates who died within 7 days of life, and 20 infants who died between 8 and 28 days. In 56 cases, the middle ear was aerated or contained a small amount of clear fluid. In 55 cases, amniotic debris was present; in 2 additional cases, cellular material was mixed with mucus. A purulent exudate was present in the middle ear of 17 infants; these exudates were cultured, and a bacterial pathogen was isolated from 13. Amniotic material was present in specimens obtained from most of the stillborn infants. Purulent exudate was not seen in the stillborns; the frequency of its presence increased with postnatal age at time of death. Of the 20 infants who lived for 7 or more days, 11 had purulent exudate in the middle ear. Each of the 17 infants with otitis media had one or more significant infections elsewhere; 12 had pneumonia, and 6 had meningitis. deSa [95] subsequently identified mucosal metaplasia and chronic inflammation in the middle ears of newborns receiving ventilatory support.

Factors that may affect the development of otitis media in the neonate include the nature of the amniotic fluid, the presence of other infectious processes, the need for resuscitative efforts (especially positive-pressure ventilation), the presence of anatomic defects such as cleft palate, the immunologic status of the infant, and the general state of health of the infant. Aspiration of infected amniotic fluid through the eustachian tube may be one factor in the development of otitis media in the neonate; dysfunction of the eustachian tube, which is shorter, wider, and more horizontal than in the older child, and failure to clear aspirated material from the middle ear probably have etiologic roles as well [96,97]. Piza and associates [98] speculated that infants born through thick meconium fluid may be at greater risk for otitis media because of the inflammatory nature of this fluid. deSa [90] noted that many infants in whom otitis media developed had required assistance in respiration and speculated that the pressure of ventilation efforts was responsible for propelling infected material into the middle ear. In infants, as in older children, middle ear effusion seems to be frequent in patients with nasotracheal tubes, and the effusion occurs first on the side of intubation [99]. Berman and colleagues [100] described an association between nasotracheal intubation for more than 7 days and the presence of middle ear effusion.

Infants with cleft palate are at high risk for recurrent otitis media and conductive hearing loss owing to the persistence of middle ear effusion. Attempts to reduce the incidence of permanent hearing impairment have included intensive monitoring of children with cleft palate for middle ear effusion and repair of these defects earlier in infancy. One study found, however, that early cleft palate repair did not reduce significantly the subsequent need for ventilating tubes in these children [101].

Breast-fed infants are at lower risk than bottle-fed infants for acute otitis media. Results of studies of Canadian Eskimo infants [102] and of infants in India [103], Finland [104], Denmark [105], and the United States [106] indicate a significant decrease in the incidence of infection of the middle ear in breast-fed infants compared with bottle-fed infants. A study from Cooperstown, New York, identified a significantly lower incidence of acute lower respiratory tract infection in infants who were breast-fed compared with infants who were bottle-fed; the incidence of otitis media was lower in the breast-fed infants, but this difference was not statistically significant [107]. Infants in Boston who were breast-fed had a lower risk for either having had one or more episodes of acute otitis media or having had recurrent acute otitis media (three or more episodes) during the first year of life. The protective association of breast-feeding did not increase with increased duration of breast-feeding; infants who were breast-fed for 3 months had an incidence of otitis media in the first year of life that was as low as infants who were breast-fed for 12 months [108].

The beneficial effects of breast-feeding may be due to immunologic factors in breast milk or to development of musculature in the breast-fed infant that may affect eustachian tube function and assist in promoting drainage of middle ear fluid. Alternatively, the findings could indicate harmful effects of bottle-feeding, including the reclining or horizontal position of the bottle-fed infant that allows fluid to move readily into the middle ear [109,110], allergy to one or more components in cow's milk or formula, or aspiration of fluids into the middle ear during feeding. The hypothesis that breast milk is protective is substantiated by the results of studies of a special feeding bottle for infants with cleft palate. Among infants who were fed by this bottle containing breast milk, the number of days with middle ear effusion was less than in infants fed by this device containing formula, which suggests that protection was more likely to be a quality of the milk, rather than of the mode of feeding [111]. Adherence of *S. pneumoniae* and *Haemophilus influenzae* to buccal epithelial cells was inhibited by human breast milk [112].

Early onset of pneumococcal otitis media has been associated with low levels of cord blood pneumococcal

IgG antibodies. Among a group of infants who had siblings with middle ear disease, low concentrations of cord blood antibody to pneumococcal serotype 14 or 19F were associated with earlier onset of otitis media [113]. Low cord blood antibody concentrations to serotype 19F predicted more episodes of otitis media over the first year of life in a cohort of 415 infants whose mothers enrolled in the study during pregnancy [114]. In these infants, early otitis media was associated significantly with type 14 IgG1 in the lowest quartile, but not with type 19F IgG1 antibody or with either IgG2 antibody [115]. These findings prompted study of maternal immunization to prevent pneumococcal disease in neonates. Immunization of pregnant chinchillas with heptavalent pneumococcal vaccine resulted in reduced incidence and severity of experimental otitis in their infants [116]. Immunization of pregnant women in Bangladesh, the Gambia, the Philippines, and the United States with pneumococcal polysaccharide vaccine resulted in pneumococcal antibody concentrations that were higher at birth in infants of immunized mothers than in controls [117–120]. In addition, pneumococcal IgG antibody acquired by infants of immunized mothers had greater opsonophagocytic activity than that in control infants [119].

Antibody to pneumococci in breast milk has been proposed to have a role in prevention of early otitis media. Early colonization with pneumococci or other bacteria is associated with early otitis media [121]. The role of antibodies to pneumococci in human milk in prevention of nasopharyngeal colonization of infants with pneumococci is controversial. A study in Sweden involving 448 mother-infant pairs failed to show reduction in carriage of pneumococci in neonates fed milk with anticapsular and antiphosphorylcholine activity and showed an increase in colonization when infants were fed milk with anti–cell wall polysaccharide antibody activity [122]. Maternal immunization with pneumococcal polysaccharide vaccine resulted in higher breast milk IgA antibodies to serotype 19F, but not type 6B [117].

## EPIDEMIOLOGY

The incidence of acute otitis media or middle ear effusion in the newborn is uncertain because of the paucity of definitive studies. Warren and Stool [123] examined 127 consecutive infants with birth weight less than 2300 g and found 3 with middle ear effusions (at 2, 7, and 26 days of life). Jaffe and coworkers [124] examined 101 Navajo infants within 48 hours of birth and identified 18 with impaired mobility of the tympanic membrane. Berman and colleagues [100] identified effusion in the middle ear of 30% of 125 consecutively examined infants who were admitted to a neonatal intensive care unit. The clinical diagnosis was corroborated by aspiration of middle ear fluid. The basis for the differences in incidence in the various studies is uncertain, but there may be an association with procedures used in the nurseries.

Acute otitis media is common in early infancy. In the prospective study of Boston children, 9% of children had an episode of middle ear infection by 3 months of age [108]. Age at the time of first episode of acute otitis media seems to be an important predictor for recurrent otitis media [108,124,125]. Children who experience a first episode during the first months of life are more likely to experience repeated infection than children whose first episode occurs after the first birthday. Additional risk factors include parental smoking and low socioeconomic status [126,127].

Some host factors that also are present in infants with neonatal sepsis have been identified in infants with middle ear infection. The incidence of infection is higher in premature infants than in infants delivered at term in some studies [128,129], but not in the prospective study of Boston children [108]. Male infants are more frequently infected than female infants [128]. Otitis media also is associated with a prolonged interval after rupture of maternal membranes and with other obstetric difficulties [90,130]. Middle ear infection is more severe in Native Americans and Canadian Eskimos than in the general population, and it is likely that this is true in neonates and older infants as well [102,124]. Children with cleft palate have a high incidence of otitis media, which may begin soon after birth [131]. Prenatal, innate, and early environmental exposures were assessed in relation to early otitis media in a cohort of 596 infants followed prospectively from birth. In multivariable analysis, prenatal factors were not associated with early onset of otitis media, but environmental (day care, upper respiratory infection, birth in the fall) and innate factors (parental and sibling history of otitis media) were associated with early or recurrent otitis media, or both [132].

## MICROBIOLOGY

The bacteriology of otitis media in infants has been studied by investigators in Honolulu [128], Dallas [129], Huntsville [133], Boston [133], Denver [97,100], Milwaukee [134], Tampere Hospital in Finland [135], and Beer-Sheva, Israel (Table 7–1) [136]. *S. pneumoniae* and *H. influenzae* are isolated frequently from fluid aspirated from the middle ear in very young infants, as is the case in older infants and children. Although it has been suggested that otitis media in the youngest neonates (<2 weeks of age) is caused more frequently by organisms associated with neonatal sepsis, such as GBS, *S. aureus*, and gram-negative enteric bacilli, this pattern does not emerge consistently when multiple studies are examined. Pneumococci were isolated from middle ear fluid in the first 2 weeks of life, and otitis associated with gram-negative enteric organisms and GBS occurred in older infants. Microbiology of middle ear disease in infants who are in neonatal intensive care nurseries may be an exception to the pattern associated with otitis media in previously healthy infants and may reflect pathogens present in the neonatal intensive care unit. In a small series of 13 such infants, only gram-negative enteric organisms and staphylococcal species were identified in the 10 samples of middle ear fluid from which bacteria were identified [100]. Table 7–1 shows the microbiology of middle ear isolates from eight studies of otitis media in infants; when possible, data from the youngest neonates have been separated from data from older infants.

Susceptibility patterns of organisms causing otitis media in newborns reflect local patterns. Generally, trends toward increasing resistance of pneumococci to antibacterial agents and colonization and disease resulting from pneumococcal serotypes not present in the pneumococcal conjugate vaccine used routinely in the United States and other countries have been observed.

Gram-negative enteric bacilli have been the predominant organisms isolated at autopsy from purulent effusions of the middle ear. Of 17 infants studied by deSa [90], 7 were found to have *E. coli*, and 6 had *P. aeruginosa*. β-hemolytic streptococci (not further identified) were isolated from one infant, and no organism was recovered from the remaining three infants. Because pneumonia and meningitis accompanied otitis in all of these cases, the predominance of gram-negative pathogens in this series is not unexpected.

Congenital tuberculosis of the ear [137] and of the ear and parotid gland [138] has been reported in preterm infants from Hong Kong and Turkey. Both cases were notable for significant regional lymphadenopathy, lack of response to antibacterial therapy, and presence of active pulmonary tuberculosis in the mother. Authors of both reports suggest that there is continued need for a high index of suspicion for this disease in appropriate circumstances. Otitis media and bacteremia resulting from *P. aeruginosa* occurring at 19 days of life was thought to occur after inoculation of the organism during a water birth [139]. *B. pertussis* was isolated from middle ear fluid in a 1-month-old infant hospitalized with pertussis; intubation of the infant's airway may have facilitated spread of the organism from the nasopharynx to the middle ear [140].

## DIAGNOSIS

During the first few weeks of life, examination of the ear requires patience and careful appraisal of all of the structures of the external canal and the middle ear [141]. The diagnostic criteria for acute otitis media in the neonate are the same as in the older child: presence of fluid in the middle ear accompanied by signs of acute illness. Middle ear effusion and its effect on tympanic membrane mobility are best measured with a pneumatic otoscope. The normal tympanic membrane moves inward with positive pressure and outward with negative pressure. The presence of fluid in the middle ear dampens tympanic membrane mobility.

In the first few days of life, the ear canal is filled with vernix caseosa; this material is readily removed with a small curette or suction tube. The canal walls of the young infant are pliable and tend to expand and collapse with insufflation during pneumatic otoscopy. Continuing pneumatic insufflation as the speculum is advanced is helpful because the positive pressure expands the pliable canal walls. The tympanic membrane often appears thickened and opaque, and mobility may be limited during the first few days of life [142]. In many infants, the membrane is in an extreme oblique position, with the superior aspect proximal to the observer (Fig. 7–1). The tympanic membrane and the superior canal wall may appear to lie almost in the same plane, so it is often difficult to distinguish the point where the canal ends and the pars flaccida of the membrane begins. The inferior canal wall may bulge loosely over the inferior position of the tympanic membrane and move with positive pressure, simulating movement of the tympanic membrane. The examiner must distinguish between the movement of the canal walls and the movement of the membrane.

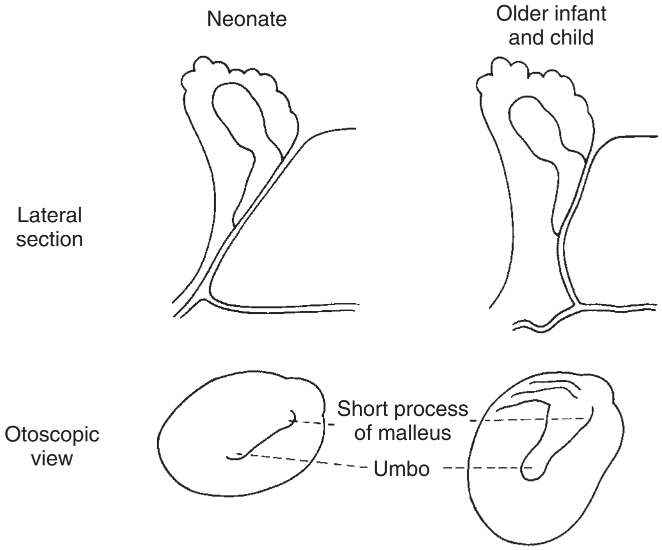

**FIGURE 7–1** Lateral section of middle ear and otoscopic view of tympanic membrane in the neonate and older infant and child. *(Courtesy of Charles D. Bluestone, MD.)*

The following considerations are helpful in recognition of these structures: Vessels are seen within the tympanic membrane, but are less apparent in the skin of the ear canal; the tympanic membrane moves during crying or respiration when the middle ear is aerated. The ear canals of most neonates permit entry of only a 2-mm-diameter speculum. Because the entire eardrum cannot be examined at one time, owing to the small diameter of the speculum, quadrants must be examined sequentially. By 1 month of age, the infant's tympanic membrane has assumed an oblique position that is less marked than in the first few weeks of life and is similar to the position in the older child.

Tympanometry is of limited value in diagnosis of middle ear effusion in the neonate. The flat tympanogram indicative of effusion in children 6 months of age or older often is not present in younger infants, even when fluid is documented by aspiration [143]. Acoustic reflectometry may be advantageous compared with tympanometry in the neonate because it does not require insertion into the ear canal or the achievement of a seal within the canal, but there are insufficient data to identify sensitivity and specificity [144].

Culture of the throat or nasopharynx is an imperfect method of identifying the bacterial pathogens responsible for otitis media. Many studies have shown the diagnostic value of needle aspiration of middle ear effusions (tympanocentesis) in acute otitis media. The specific microbiologic diagnosis defines the appropriate antimicrobial therapy and is sufficiently important in the sick neonate to warrant consideration of aspiration of the middle ear fluid. Aspiration of middle ear fluid is more difficult in

the neonate than in the older child, and usually the assistance of an otolaryngologist (using an otoscope with a surgical head or an otomicroscope) is required.

When spontaneous perforation has occurred, the fluid exuding into the external canal from the middle ear is contaminated by the microflora from the canal. Appropriate cultures may be obtained by carefully cleaning the canal with 70% alcohol and obtaining cultures from the area of perforation as the fluid emerges or by needle aspiration through the intact membrane.

### TREATMENT

Initial therapy for febrile or ill-appearing infants with otitis media during the first 2 weeks of life is similar to therapy for infants with neonatal sepsis. A penicillin and an aminoglycoside or third-generation cephalosporin should be used. Specific therapy can be provided if needle aspiration is performed and the pathogen is identified. Infants who remain in the nursery because of prematurity, low birth weight, or illness require similar management during the first 4 to 6 weeks of life. If the infant was born at term, had a normal delivery and course in the nursery, has been in good health since discharge from the nursery, is not ill-appearing, and is 2 weeks of age or older, the middle ear infection probably is due to *S. pneumoniae* or *H. influenzae* and may be treated with an appropriate oral antimicrobial agent such as amoxicillin or amoxicillin-clavulanate [145]. The infant may be managed outside the hospital if he or she does not seem to have a toxic condition. For infants born at term who have acute otitis media and are in a toxic condition, the physician must consider hospitalization, cultures of blood and cerebrospinal fluid, and use of parenterally administered antimicrobial agents because of possible systemic infection, a focus of infection elsewhere, or presence of a resistant organism.

### PROGNOSIS

Infants who have infections of the middle ear in the neonatal period seem to be susceptible to recurrent episodes of otitis media [108,124,125]. The earlier in life an infant has an episode of otitis media, the more likely he or she is to have recurrent infections. It is uncertain whether this means that an early episode of otitis media damages the mucosa of the middle ear and makes the child more prone to subsequent infection, or whether early infection identifies children with dysfunction of the eustachian tube or subtle or undefined immune system abnormalities who have a propensity to infection of the middle ear because of these abnormalities.

## MASTOIDITIS

The mastoid air cells are not developed at birth and usually consist of only a single space each. Mastoiditis rarely occurs in neonates. One report cited a case of meningitis and mastoiditis caused by *H. influenzae* in a newborn [146]. Radiographs of the mastoid area showed a cloudy right antrum. At operation, the middle ear was normal, but the antrum was filled with infected mesenchymal tissue.

## PNEUMONIA

Pneumonia, inflammation of the lungs, in the fetus and newborn can be classified into four categories according to the time and mode of acquisition of inflammation:

1. *Congenital pneumonia acquired by the transplacental route*: Pneumonia is one component of generalized congenital disease.
2. *Intrauterine pneumonia*: This is an inflammatory disease of the lungs found at autopsy in stillborn or live-born infants who die within the first few days of life, usually associated with fetal asphyxia or intrauterine infection, and includes infectious and noninfectious causes.
3. *Pneumonia acquired during birth*: Signs of pneumonia occur within the first few days of life, and infection is due to microorganisms that colonize the maternal birth canal.
4. *Pneumonia acquired after birth*: The illness manifests during the first month of life, either in the nursery or at home; sources of infection include human contacts and contaminated equipment.

Although helpful as a general framework for understanding neonatal pneumonia, these four categories have clinical features and pathologic characteristics that overlap. Management of pneumonia is essentially the same for all four categories, requiring aggressive supportive measures for the respiratory and circulatory systems along with treatment for the specific underlying infectious disorder.

Pneumonia in the neonate may be caused by viruses, bacteria, or parasitic organisms. Detailed information about causative organisms mentioned in this chapter other than bacteria is found in the appropriate chapters in this book; bacterial disease is covered in detail here.

Pneumonia acquired by the transplacental route may be caused by rubella, cytomegalovirus, herpes simplex virus, adenoviruses [147], mumps virus [148], *Toxoplasma gondii*, *L. monocytogenes*, or *T. pallidum*. Some of these organisms and enteroviruses, genital mycoplasmas, *M. pneumoniae* [148a], *C. trachomatis*, and *Mycobacterium tuberculosis* are also responsible for intrauterine pneumonia resulting from aspiration of infected amniotic fluid. Fatal pneumonitis caused by echovirus has also been reported in newborns (see Chapter 24) [149]. Isolation of *Trichomonas vaginalis* from the tracheal aspirates of infants with pneumonia suggests a possible association of this organism with respiratory tract disease in the neonate [150,151].

GBS is the most frequent cause of bacterial pneumonia acquired at delivery. Pneumonia caused by GBS and other bacteria such as *E. coli* or *L. monocytogenes* may resemble hyaline membrane disease.

Pneumonias acquired after birth, either in the nursery or at home, include those caused by respiratory viruses such as respiratory syncytial virus, influenzavirus, or adenoviruses; gram-positive bacteria such as pneumococci and *S. aureus*; gram-negative enteric bacilli; *Legionella pneumophila* [151a] *C. trachomatis*; *Mycoplasma*; and *Pneumocystis carinii* [152]. A fatal case of adenovirus serotype 14 with pathologic features consistent with bronchiolitis and acute respiratory distress syndrome occurred in a 12-day-old infant in 2006 [153]. Pneumonia caused by nonbacterial

microorganisms is discussed in the appropriate chapters. Bacterial pneumonia and neonatal sepsis acquired during or soon after birth share many features of pathogenesis, epidemiology, and management, and these aspects are discussed in Chapter 6. Discussion of pneumonia in the fetus and newborn not presented elsewhere in the text follows.

## PATHOGENESIS AND PATHOLOGY

### Congenital or Intrauterine Pneumonia

Histologic features of congenital or intrauterine pneumonia have been described from autopsy findings in infants who are stillborn or who die shortly after birth (usually within 24 hours). An inflammatory reaction is found in histologic sections of lung. Polymorphonuclear leukocytes are present in the alveoli and often are mixed with vernix and squamous cells. Infiltrates of round cells may be present in interstitial tissue of small bronchioles and interalveolar septa [154–159]. Alveolar macrophages may be present and have been associated with duration of postnatal life and inflammatory pulmonary lesions [160]. The inflammation is diffuse and usually is uniform throughout the lung. Bacteria are seen infrequently, and cultures for bacteria are often negative. Davies and Aherne [157] noted that the usual characteristics of bacterial pneumonia are missing in congenital pneumonia; among these characteristics are pleural reaction, infiltration or destruction of bronchopulmonary tissue, and fibrinous exudate in the alveoli.

The pathogenesis of congenital pneumonia is not well understood [161]. Asphyxia and intrauterine infection, acting alone or together, seem to be the most important factors [157]. It is thought that microorganisms of the birth canal contaminate the amniotic fluid by ascending infection after early rupture of maternal membranes or through minimal and often unrecognized defects in the membranes. Evidence of aspiration of amniotic fluid is frequent [157]. Naeye and colleagues [162–164] proposed that microbial invasion of the fetal membranes and aspiration of infected amniotic fluid constitute a frequent cause of chorioamnionitis and congenital pneumonia. Bacteriologic studies have produced equivocal results, however. Many infants with congenital pneumonia do not have bacteria in their lungs, yet cultures of the lung of some infants without pneumonia do yield bacteria [165]. Fetal asphyxia or hypoxia seems to be a factor in most cases of congenital pneumonia. The asphyxia may cause death directly or by eliciting a pulmonary response consisting of hemorrhage, edema, and inflammatory cells. From his studies of congenital pneumonia, Barter [166] concluded that hypoxia or infection may produce similar inflammation in the lungs. In addition, Bernstein and Wang [167] found that evidence of fetal asphyxia was frequently present at autopsy in infants with congenital pneumonia who also had generalized petechial hemorrhage, subarachnoid and intracerebral hemorrhage, liver cell necrosis, or ulceration of the gastrointestinal mucosa.

Although it is likely that asphyxia and infection can produce similar inflammatory patterns in lungs of the fetus, available information is insufficient to determine which is more important or more frequent. In a review of fetal and perinatal pneumonia, Finland [168] concluded that "pulmonary lesions certainly play a major role in the deaths of the stillborn and of infants in the early neonatal period. Infection, on the other hand, appears to play only a minor role in what has been called 'congenital pneumonia,' that is, the inflammatory lesion seen in the stillborn or in those dying within the first few hours, or possibly the first day or two; it assumes greater importance in pneumonias that cause death later in the neonatal period." Davies [169] noted that the histologic presentation of congenital pneumonia seems to represent aspiration of materials in amniotic fluid, including maternal leukocytes and amniotic debris, rather than infection originating in the pulmonary air spaces. Evidence of infiltration of alveoli or destruction of bronchopulmonary tissue is rarely present.

### Pneumonia Acquired during the Birth Process and in the First Month of Life

The pathology of pneumonia acquired during or after birth is similar to the pathology found in older children or adults. The lung contains areas of densely cellular exudate with vascular congestion, hemorrhage, and pulmonary necrosis [157,167,170]. Bacteria often are seen in sections of the lung. *S. aureus* (see Chapter 14) and *Klebsiella pneumoniae* [171,172] may produce extensive tissue damage, microabscesses, and empyema. Pneumatoceles are a common manifestation of staphylococcal pneumonia, but also may occur in infections with *K. pneumoniae* [171,172] and *E. coli* [173]. Hyaline membranes similar to those seen in respiratory distress syndrome have been observed in the lungs of infants who died with pneumonia caused by GBS. Cocci were present within the membranes, and in some cases, exuberant growth that included masses of organisms was apparent. Although most thoroughly documented in cases of pneumonia caused by GBS, similar membranes have been seen in histologic sections of the lungs of infants who died with pneumonia caused by *H. influenzae* and gram-negative enteric bacilli [174].

The pathogenesis of pneumonia acquired at or immediately after birth is similar to the pathogenesis of neonatal sepsis and is discussed in Chapter 6. Presumably, aspiration of infected amniotic fluid or secretions of the birth canal are responsible for most cases of pneumonia acquired during delivery. After birth, the infant may become infected through human contact or contaminated equipment. Infants who receive assisted ventilation are at risk because of the disruption of the normal barriers to infection owing to the presence of the endotracheal tube and possible irritation of tissues near the tube. Bacteria or other organisms may invade the damaged tissue, which may result in tracheitis or tracheobronchitis [175]. A more recent study identified biofilm formation on endotracheal tubes from infants and hypothesized a relationship between biofilm formation and lower respiratory tract infection in intubated neonates [176].

Ventilator-associated pneumonia may be prevented by reducing bacterial colonization of the aerodigestive tract and decreasing the incidence of aspiration. A review highlighted strategies for prevention of pneumonia in patients receiving mechanical ventilation, including nonpharmacologic strategies such as attention to hand washing and

standard precautions, positioning of patients, avoiding abdominal distention, avoiding nasal intubation, and maintaining ventilator circuits and suction catheters and tubing, and pharmacologic strategies such as appropriate use of antimicrobial agents [177]. Newborns with congenital anomalies, such as tracheoesophageal fistula, choanal atresia, and diaphragmatic hernia, have an increased risk of developing pneumonia.

Lung abscess and empyema are uncommon in neonates and usually occur as complications of severe pneumonia. Abscesses also may occur as a result of infection of congenital cysts of the lung.

## MICROBIOLOGY

Most information about the bacteriology of fetal and neonatal pneumonia has been derived from studies done at autopsy of stillborn infants and of infants who die during the first month of life. A study reviewing causes of death of infants with very low birth weight concluded, on the basis of histologic studies done at autopsy, that pneumonia was an underrecognized cause of death in these infants [178]. Barter and Hudson [165] reported bacteriologic studies at autopsy of infants with and without pneumonia. The incidence of bacteria in the lungs increased with age in infants dying with and without pneumonia. Among the infants with pneumonia, bacteria were cultured from the lungs of 55% of stillborn infants and infants who died during the first day of life, 70% of infants who died between 24 hours and 7 days of age, and 100% of infants who died between 7 and 28 days of age. Among the infants without pneumonia, bacteria were cultured from the lungs of 36% of stillborn infants and infants who died within the first 24 hours, 53% of infants who died between 24 hours and 7 days of age, and 75% of infants who died between 7 and 28 days of age. The bacterial species were similar in the infants with and without pneumonia, with the exception of GBS, which was found only in infants with pneumonia.

These results were corroborated by Penner and McInnis [159]. Bacteria were cultured from 92% of the lungs of fetuses and neonates with pneumonia and from 40% of the lungs of fetuses and neonates without pneumonia. Davies [179] did lung punctures in stillborn and live-born infants immediately after death, and bacteria were cultured from the lungs of 74% of 93 infants, although pneumonia was diagnosed in only 9 cases. Barson [180] identified bacteria in lung cultures at autopsy of 252 infants dying with bronchopneumonia; positive cultures were obtained in 60% of infants dying on the first day of life and in 78% of infants dying between 8 and 28 days of age. Bacteria were cultured at autopsy from the lungs of many infants with and without pneumonia. Information about bacterial etiology of pneumonia also can be obtained by culturing blood, tracheal aspirates, and pleural fluid and by needle aspiration of the lungs of living children with pneumonia.

The bacterial species responsible for fetal and neonatal pneumonia are those present in the maternal birth canal; included in this flora are gram-positive cocci such as group A, group B, and group F [181] streptococci and gram-negative enteric bacilli, predominantly *E. coli* and, to a lesser extent, *Proteus*, *Klebsiella*, and *Enterobacter* species. For infants who remain hospitalized, microorganisms acquired postnatally may reflect the microbial environment of the inpatient setting. For infants who develop pneumonia in the community, typical organisms causing community-acquired pneumonia predominate. In the 1950s and 1960s, *S. aureus* was a common cause of neonatal pneumonia.

Few data exist about relative frequency of specific etiologic agents of neonatal pneumonia or incidence of pneumonia caused by specific organisms. One review of invasive pneumococcal disease monitored prospectively by the U.S. Pediatric Multicenter Pneumococcal Surveillance Group identified 29 cases of pneumococcal infection in infants younger than 30 days of age among 4428 cases in children; 4 of these were bacteremic pneumonia [182]. In addition to *S. pneumoniae* [183–185], *H. influenzae* [174,186] and *Moraxella catarrhalis* [187] also are infrequent causes of pneumonia in newborns. Pneumonia caused by these organisms is frequently associated with bacteremia and sometimes with meningitis [157,183,185,186]. Many other organisms have been reported in association with pneumonia in neonates, including a fatal case of congenital pneumonia caused by *Pasteurella multocida* in a full-term neonate associated with maternal infection and colonization of the family cat with the same organism [188]. A case of pneumonia and sepsis caused by ampicillin-resistant *Morganella morganii* was reported from Texas [189]; the authors speculate about the role of increased use of intrapartum antibiotics in predisposing to colonization and infection with ampicillin-resistant organisms. A case of pneumonia due to *Legionella pneumophila* occurred in a newborn following water birth [189a].

Certain bacteria are associated with a predilection for developing lung abscess or empyema. During the 1950s and 1960s, outbreaks of staphylococcal pneumonia occurred; many times these infections were accompanied by empyemas and pneumatoceles. Although rare in newborns, *H. influenzae* was associated with pneumonia and empyema [190] until its virtual disappearance after initiation of universal immunization in the early 1990s. Single or multiple abscesses may also be caused by GBS, *E. coli*, and *K. pneumoniae* [191,192]. Cavitary lesions may develop in pneumonia caused by *Legionella pneumophila* [193]. Lung abscess and meningitis caused by *Citrobacter koseri* was reported in a previously healthy 1-month-old infant [194]. Nosocomial infection secondary to *L. pneumophila* has been reported, including cases of fatal necrotizing pneumonia and cavitary pneumonia [195]. Reports have identified *Citrobacter diversus* as a cause of lung abscess [196] and *Bacillus cereus* as a cause of a necrotizing pneumonia in premature infants [197].

Empyema can also be associated with extensive pneumonia. Empyema secondary to *E. coli* and *Klebsiella* has been reported in 6- and 8-day-old infants [198], and *Serratia marcescens* was isolated from blood, tracheal aspirate, and empyema fluid in a premature neonate [199]. The past decade was characterized by emergence of increased incidence of invasive disease secondary to group A streptococci. Cases of pleural empyema secondary to group A streptococci have been reported from the United Kingdom and Sweden [200,201].

# EPIDEMIOLOGY

## Incidence

Table 7–2 presents the incidence of pneumonia at autopsy of stillborn and live-born infants. Pneumonia is a significant cause of death in the neonatal period [202], and infection of amniotic fluid leading to pneumonia may be the most common cause of death in extremely premature infants [203]. The definition of pneumonia in the autopsy studies usually was based on the presence of polymorphonuclear leukocytes in the pulmonary alveoli or interstitium or both. The presence or absence of bacteria was not important in the definition of pneumonia. The incidence rates for congenital and neonatal pneumonia at autopsy are similar despite the different periods of study (1922-1999) and different locations [154–156,158,167,178,201–205] (with the single exception of a report from Helsinki [170]): 15% to 38% of stillborn infants and 20% to 32% of live-born infants had evidence of pneumonia. The incidence rates for pneumonia were similar in premature and in term infants. Rates of pneumonia derived from epidemiologic studies are scarce. Sinha and colleagues [206] reported an attack rate of 0.4 per 100 infants diagnosed during a nursery stay, and 0.03 and 0.01 per 100 infants diagnosed at pediatric office visits and in hospital or emergency department visits. They acknowledged a paucity of data with which to compare their rates, which they derived from retrospective review of data from a large health maintenance organization.

## Race and Socioeconomic Status

In two studies, black infants had pneumonia at autopsy significantly more often than white infants. The Collaborative Study of the National Institutes of Health [205] considered the incidence of pneumonia in live-born infants who died within the first 48 hours of life: 27.7% of black infants had evidence of pneumonia, whereas only 11.3% of white infants showed signs of this disease, and this difference was present in every weight group. In New York City, Naeye and coworkers [162] studied 1044 consecutive autopsies of newborn and stillborn infants; black infants had significantly more pneumonia (38%) than Puerto Rican infants (22%) or white infants (20%). The same study showed that the incidence of pneumonia in infants was inversely related to the level of household income. Infants from the families with the lowest income had significantly more pneumonia than infants from the families with the highest income. At comparable levels of household income, black infants had a higher incidence of neonatal pneumonia than Puerto Rican or white infants. These racial and economic differences were not readily explained by the authors or by other investigators.

## Epidemic Disease

Pneumonia may be epidemic in a nursery because of a single source of infection, such as a suppurative lesion caused by *S. aureus* in a nursery employee or contamination of a common solution or piece of equipment, usually caused by *Pseudomonas*, *Flavobacterium*, or *S. marcescens*. Infection may also spread by droplet nuclei among infants or between personnel and infants. Epidemics of respiratory infection related to viruses also have been reported (see Chapter 35).

## Developing Countries

Pneumonia is a particular threat to neonates in developing countries. A survey of a rural area in central India revealed that the mortality rate for pneumonia in the first 29 days of life was 29 per 1000 live-born children (the rate during the first year was 49.6 per 1000 live-born children) [207]. The aerobic bacteria grown from the vagina of rural women were used as a surrogate for likely pathogens of pneumonia in neonates [208]. Vaginal flora included *E. coli* and other gram-negative enteric bacilli and

staphylococcal species in expected proportions, but a relatively low rate of β-hemolytic streptococci (3.2%). Management of pneumonia cases (the cases that did not necessitate immediate referral to a hospital) included continued breast-feeding and trimethoprim-sulfamethoxazole. Because of the lack of microbiologic information, syndrome-based management of infectious diseases is encouraged in the developing world. A meta-analysis of this approach found a reduction of pneumonia mortality of 42% in neonates managed in this fashion [209].

Singhi and Singhi [210] studied the clinical signs of illness in Chandigarh infants younger than 1 month of age with radiologically confirmed pneumonia to determine how to increase accuracy of diagnosis of pneumonia by health care workers. Rural health care workers (most were illiterate) used revised World Health Organization criteria for pneumonia in infants, including respiratory rate greater than 60 breaths per minute, presence of severe chest indrawing (retraction), or both [211]. Cough and respiratory rate greater than 50 breaths per minute missed 25% of cases; decreasing the threshold respiratory rate to 40 breaths per minute increased the sensitivity. In the absence of cough, chest retraction or respiratory rate greater than 50 breaths per minute or both had maximum accuracy.

## CLINICAL MANIFESTATIONS

Onset of respiratory distress at or soon after birth is characteristic of intrauterine or congenital pneumonia. Before delivery, fetal distress may be evident: The infant may be tachycardic, and the fetal tracing may show poor beat-to-beat variability or evidence of deep decelerations. Meconium aspiration may have occurred before delivery, suggesting fetal asphyxia and gasping. The infant may have episodes of apnea or may have difficulty establishing regular respiration. In some cases, severe respiratory distress is delayed, but it may be preceded by increasing tachypnea, apneic episodes, and requirement for increasing amounts of oxygen. The infant may have difficulty feeding, temperature instability, and other signs of generalized sepsis, including poor peripheral perfusion, disseminated intravascular coagulation, and lethargy.

Infants who acquire pneumonia during the birth process or postnatally may have signs of systemic illness, such as lethargy, anorexia, and fever. Signs of respiratory distress, including tachypnea, dyspnea, grunting, coughing, flaring of the alae nasi, irregular respirations, cyanosis, intercostal and supraclavicular retractions, rales, and decreased breath sounds, may be present at the onset of the illness or may develop later. Severe disease may progress to apnea, shock, and respiratory failure. Signs of pleural effusion or empyema may be present in suppurative pneumonias associated with staphylococcal infections, group A [212] and group B streptococcal infections, and *E. coli* infections [213].

In a study of 103 neonates in New Delhi, Mathur and colleagues documented the sensitivity and specificity of signs of neonatal pneumonia: cough ($n = 13$; 14%; 100%); difficulty in feeding ($n = 91$; 88%; 6%); chest retractions ($n = 96$; 93%; 36%); flaring of alae nasi ($n = 50$; 49%; 70%) [214].

## DIAGNOSIS

### Clinical Diagnosis

A history of premature delivery, prolonged interval between rupture of maternal membranes and delivery, prolonged labor, excessive obstetric manipulation, and presence of foul-smelling amniotic fluid frequently are associated with neonatal infection, including sepsis and pneumonia. The clinical manifestations of pneumonia may be subtle and nonspecific at the onset, and specific signs of respiratory infection may not be evident until late in the course of illness. Most commonly, pneumonia is associated with evidence of respiratory distress, including tachypnea, retractions, flaring of nasal alae, and increasing requirement for oxygen.

### Radiologic Diagnosis

A chest radiograph is the most helpful tool for making the diagnosis of pneumonia. The radiograph of an infant with intrauterine pneumonia may contribute no information, however, or show only the coarse mottling of aspiration. If the radiologic examination is done early in the course of meconium or other aspiration pneumonias, typical radiologic features may not yet have developed. The radiograph of an infant with pneumonia acquired during or after birth may show streaky densities or confluent opacities. Peribronchial thickening, indicating bronchopneumonia, may be present. Pleural effusion, abscess cavities, and pneumatoceles are frequent in infants with staphylococcal infections, but also may occur in pneumonia caused by group A streptococci, *E. coli* [173], or *K. pneumoniae* [172]. Diffuse pulmonary granularity or air bronchograms similar to that seen in respiratory distress syndrome have been observed in infants with pneumonia related to GBS [215]. Computed tomography (CT) with contrast medium enhancement is beneficial in localizing pulmonary lesions such as lung abscess and distinguishing abscess from empyema, pneumatoceles, or bronchopleural fistulas [192]. Ultrasound examination was used to diagnose hydrothorax in utero at 32 weeks of gestation [216].

Although it is impossible to distinguish bacterial from viral pneumonia on the basis of a chest radiograph alone, several features may help distinguish between the two. Findings that are more characteristic of viral pneumonias include hyperexpansion, atelectasis, parahilar peribronchial infiltrates, and hilar adenopathy, which is associated almost exclusively with adenovirus infection. Alveolar disease, consolidation, air bronchograms, pleural effusions, pneumatoceles, and necrotizing pneumonias are more characteristic of bacterial processes [217].

### Microbiologic Diagnosis

Because of the difficulty in accessing material from a suppurative focus in the lower respiratory tree, microbiologic diagnosis of pneumonia is problematic. Although cultures of material obtained from lung aspiration have been shown to yield bacterial pathogens in about one third of a group of seriously ill infants with lung lesions accessible to needle aspiration [218], this rate of positive results is unlikely to be obtained in an unselected group of infants with pneumonia. Diagnosis may be based on isolating

pathogens from other sites. When generalized systemic infection is present, cultures of blood, urine, or cerebrospinal fluid may yield a pathogen. Bacteremia may be identified in about 10% of febrile children with pneumonia [219]. If a pleural effusion is present and the bacterial diagnosis is not yet evident, pleural fluid biopsy or culture or both may be helpful. Bacterial cultures of the throat and nasopharynx are unrevealing or misleading because of the high numbers of respiratory pathogens present.

Tracheal aspiration through a catheter is frequently valuable when performed by direct laryngoscopy, but the aspirate may be contaminated when the catheter is passed through the nose or mouth. Sherman and colleagues [220] performed a careful study of the use of tracheal aspiration in diagnosis of pneumonia in the first 8 hours of life. Tracheal aspirates were obtained from 320 infants with signs of cardiorespiratory disease and abnormalities on the chest radiograph; 25 infants had bacteria present in the smear of the aspirate, and the same organisms were isolated from cultures of 14 of 25 aspirates. Thureen and colleagues [221] found that tracheal aspirate cultures failed to define an infectious cause of deterioration in ventilated infants. Positive tracheal aspirates were found with equal frequency among infants with clinically suspected lower respiratory tract infection and in "well" controls. Tracheal aspirate cultures may provide useful information about potential pathogens in pneumonia or bacteremia, but rarely indicate the risk or timing of such complications [222]. Often, surveillance cultures of tracheal aspirate material are used to guide empirical therapy when a new illness develops in an infant with a prolonged course on a ventilator.

Bronchoscopy can provide visual, cytologic, and microbiologic evidence of bacterial pneumonia [223]. Aspiration of pulmonary exudate (lung puncture or "lung tap") can be used to provide direct, immediate, and unequivocal information about the causative agent of pneumonia [218]. This procedure is now performed rarely; most reports of its use in infants and young children precede the introduction of antimicrobial agents [224,225].

Open lung biopsy has been used to identify the etiology of lung disease in critically ill infants and seems to have been most helpful at a time when corticosteroids for bronchopulmonary dysplasia were withheld if there was concern about pulmonary infection. Cheu and colleagues [226] identified three infections in 17 infants who had open lung biopsies: respiratory syncytial virus in 1 infant and *Ureaplasma urealyticum* in 2 infants. Although the optimal indications for use of corticosteroids in bronchopulmonary dysplasia are controversial [227,228], generally corticosteroids are not withheld if indicated because of low likelihood of an infectious process [229].

## Histologic and Cytologic Diagnosis

The data of Naeye and coworkers [162] indicated that congenital pneumonia or pneumonia acquired during birth is almost always accompanied by chorioamnionitis, although chorioamnionitis may be present in the absence of pneumonia or other neonatal infections. These and other data [230] suggested that the presence of leukocytes in sections of placental membranes and of umbilical vessels or in Wharton jelly is valuable in diagnosing fetal and neonatal infections, including pneumonia and sepsis. Other investigators were less certain and believed that the presence of inflammation in the placenta or umbilical cord does not distinguish changes caused by hypoxia from those caused by infection [166,167].

Culture of material obtained by aspiration of stomach contents usually is not helpful in diagnosing pneumonia because this material is contaminated by the flora of the upper respiratory tract. In addition, infants with pneumonia may have no evidence of the organism in the gastric aspirate [231]. There is some evidence, however, that microscopic examination of gastric contents may be useful in defining the presence of an inflammatory process in the lung after the first day of life. Because affected infants are unable to expectorate, they swallow bronchial secretions. During the first few hours of life, inflammatory cells present in the gastric aspirate are of maternal origin; however, after the first day, any polymorphonuclear leukocytes present are those of the infant. Tam and Yeung [231] showed that if more than 75% of the cells in the gastric aspirate obtained from infants after the first day of life were polymorphonuclear leukocytes, pneumonia was usually present. A study by Pole and McAllister [232] did not confirm the value of gastric aspirate cytology in the diagnosis of pneumonia, however.

Primary ciliary dyskinesia is congenital and may manifest in the newborn period as respiratory distress. Infants with situs inversus are at risk for this condition. Consultation with a geneticist may be warranted; a biopsy specimen of nasal epithelium may be needed to identify the characteristic abnormal morphology of cilia of the immotile cilia syndrome [233–235].

## Immunologic Diagnosis

Immunologic response to various microorganisms responsible for pneumonia is used extensively as an aid to diagnosis with infections caused by GBS, *S. aureus* (see Chapters 12 and 14) and organisms that cause congenital infection (rubella virus, *T. gondii*, herpes simplex virus, cytomegalovirus, and *T. pallidum*). Giacoia and colleagues [236] prepared antigens from microorganisms isolated from bronchial aspirates and correlated specific antibodies and nonspecific IgM antibody with clinical and radiologic evidence of pneumonia. A significant immune response was identified in approximately one fourth of the patients studied. These data are of uncertain significance because of the difficulty of distinguishing immune response to organisms responsible for lower respiratory tract disease from the response to organisms colonizing the respiratory tree [237].

Although controversial, testing of blood, urine, and cerebrospinal fluid for antigens to GBS, pneumococci, *H. influenzae*, and *Neisseria meningitidis* may provide helpful information for selected infants with generalized sepsis and pneumonia [238]. Interpretation of results must take into account possible contamination by organisms colonizing the area around the urethra (in the case of a bag specimen of urine) and possible interference with the test result caused by recent immunization against *H. influenzae* type b or pneumococci or recent infection owing to

these organisms. Bedside cold agglutination testing may be helpful in the case of *Mycoplasma* infection, but the test has low sensitivity, so a negative result is not diagnostic. Although polymerase chain reaction testing has provided diagnostic information for many conditions, it does not at present offer any specific advantages in the diagnosis of pneumonia.

## DIFFERENTIAL DIAGNOSIS

Various noninfectious diseases and conditions may simulate infectious pneumonia. Respiratory distress syndrome (hyaline membrane disease), atelectasis, aspiration pneumonia, pneumothorax or pneumomediastinum, pulmonary edema and hemorrhage, pleural effusions of the lung (e.g., chylothorax), cystic lung disease, hypoplasia or agenesis, pulmonary infarct, and cystic fibrosis all have some signs and symptoms similar to pneumonia. Meconium aspirated into the distal air passages may produce chemical pneumonitis or segmental atelectasis [239]. Multifocal pulmonary infiltrates have been associated with feeding supplements containing medium-chain triglycerides [240]. Infants with immotile cilia syndrome may present within the first 24 hours of life with tachypnea, chest retraction, and rales. Results of prospective epidemiologic studies of neonatal respiratory diseases from Sweden [241] for the period 1976-1977 and from Lebanon [242] for the period 1976-1984 indicate that infection was second in frequency to hyaline membrane disease in both surveys. Avery and coworkers [243] presented clues to the diagnosis of diseases and conditions producing respiratory distress based on information from the maternal history and signs in the infant (Table 7–3).

Pneumonia may be superimposed on hyaline membrane disease. One survey showed that histologic evidence of pneumonia was present at autopsy in 16% of 1535 infants with hyaline membrane disease [244]. Foote and Stewart [245] showed, by chest radiography, that pneumonia modifies the reticulogranular pattern of hyaline membrane disease by replacing the air in the alveoli with inflammatory exudate. Any modification of the radiographic pattern typical of hyaline membrane disease should lead the physician to consider superinfection.

Ablow and colleagues [246] reported that infants with pneumonia caused by GBS who also showed clinical and radiologic signs of respiratory distress syndrome were easier to ventilate than infants who had hyaline membrane disease with a clinical picture suggestive of respiratory distress syndrome unassociated with infection. These findings are of limited value in identifying infection in individual infants and were not confirmed in a subsequent study by Menke and colleagues [247].

Pleural fluid, usually limited to the lung fissures, occurs in many infants and may be related to slow resorption of fetal lung fluid, to transient tachypnea of the newborn, or to respiratory distress syndrome of noninfectious etiology. Large collections of fluid in the pleural space may represent bacterial empyema; noninfectious causes include chylothorax, hydrothorax (associated with hydrops fetalis, congestive heart failure, or transient tachypnea), meconium aspiration pneumonitis, or hemothorax related to hemorrhagic disease of the newborn.

**TABLE 7–3** Clues to Diagnosis of Types of Respiratory Distress

| Information from Maternal History | Most Probable Condition in Infant |
|---|---|
| Peripartum fever | Pneumonia |
| Foul-smelling amniotic fluid | Pneumonia |
| Excessive obstetric manipulation at delivery | Pneumonia |
| Infection | Pneumonia |
| Premature rupture of membranes | Pneumonia |
| Prolonged labor | Pneumonia |
| Prematurity | Hyaline membrane disease |
| Diabetes | Hyaline membrane disease |
| Hemorrhage in days before premature delivery | Hyaline membrane disease |
| Meconium-stained amniotic fluid | Meconium aspiration |
| Hydramnios | Tracheoesophageal fistula |
| Pain medications | CNS depression |
| Use of reserpine | Stuffy nose |
| Traumatic or breech delivery | CNS hemorrhage; phrenic nerve paralysis |
| Fetal tachycardia or bradycardia | Asphyxia |
| Prolapsed cord or cord entanglements | Asphyxia |
| Postmaturity | Aspiration |
| Amniotic fluid loss | Hypoplastic lungs |
| **Signs in the Infant** | **Most Probable Associated Condition** |
| Single umbilical artery | Congenital anomalies |
| Other congenital anomalies | Associated cardiopulmonary anomalies |
| Situs inversus | Kartagener syndrome |
| Scaphoid abdomen | Diaphragmatic hernia |
| Erb palsy | Phrenic nerve palsy |
| Inability to breathe with mouth closed | Choanal atresia; stuffy nose |
| Gasping with little air exchange | Upper airway obstruction |
| Overdistention of lungs | Aspiration; lobar emphysema or pneumothorax |
| Shift of apical pulse | Pneumothorax, chylothorax, hypoplastic lung |
| Fever or increase in body temperature in constant-temperature environment | Pneumonia |
| Shrill cry, hypertonia or flaccidity | CNS disorder |
| Atonia | Trauma, myasthenia, poliomyelitis, amyotonia |
| Frothy blood from larynx | Pulmonary hemorrhage |
| Head extended in the absence of neurologic findings | Laryngeal obstruction or vascular rings |
| Choking after feedings | Tracheoesophageal fistula or pharyngeal incoordination |
| Plethora | Transient tachypnea |

*CNS, central nervous system.*
*From Avery ME, Fletcher BD, Williams RG. The Lung and Its Disorders in the Newborn Infant. Philadelphia, WB Saunders, 1981.*

The symptoms of cystic fibrosis may begin in early infancy. Of patients with newly diagnosed cases seen in a 5-year period at Children's Hospital Medical Center in Boston, 30% were younger than 1 year of age [248]. The authors described the histories of four children whose respiratory symptoms began before the infants were 1 month of age. The clinical course of the disease in young infants is characterized by a bronchiolitis-like syndrome with secondary chronic obstructive pulmonary disease and respiratory distress, coughing, wheezing, poor exchange of gases, cyanosis, hypoxia, and failure to thrive.

## MANAGEMENT

Infants with bacterial pneumonia must receive prompt treatment with appropriate antimicrobial agents. Culture of blood and urine may identify a bacterial pathogen, especially in patients with generalized sepsis. Cerebrospinal fluid culture may be helpful if the infant is not too unstable for lumbar puncture. In intubated infants, tracheal aspirate smears may indicate the presence of inflammatory cells, and cultures may provide information about organisms colonizing the trachea.

Because the microbiology of pneumonia in the newborn is the same as that of sepsis, the guidelines for management discussed in Chapter 6 are applicable. Initial antimicrobial therapy should include a penicillin (penicillin G or ampicillin) or a penicillinase-resistant penicillin (if staphylococcal infection is a possibility) and an aminoglycoside or a third-generation cephalosporin. In situations in which resistant pneumococci or methicillin-resistant *S. aureus* may be the cause of the pneumonia, vancomycin may be used for initial therapy until microbiologic data are available. The oxazolidinone antibiotic linezolid, an agent with a unique mechanism of action with activity against gram-positive organisms, has been studied in neonates. Sixty-three neonates with known or suspected resistant gram-positive infections were randomly assigned to receive linezolid or vancomycin. No difference in efficacy of the two agents was noted, and the authors concluded that linezolid is a safe and effective alternative to vancomycin in treatment of resistant gram-positive infections [249].

Duration of therapy depends on the causative agent: pneumonia caused by gram-negative enteric bacilli or GBS is treated for 10 days; disease caused by *S. aureus* may require 3 to 6 weeks of antimicrobial therapy according to the severity of the pneumonia and the initial response to therapy. Empyema or lung abscesses may also require longer courses of therapy.

When clinical and radiologic signs of hyaline membrane disease are present, infection caused by GBS or gram-negative organisms, including *H. influenzae*, is not readily distinguished from respiratory distress syndrome of noninfectious etiology. Until techniques are developed that can distinguish infectious from noninfectious causes of respiratory distress syndrome, it is reasonable to treat all infants who present with clinical and radiologic signs of the syndrome. Therapy is instituted for sepsis, as outlined earlier, after appropriate cultures have been taken. If the results of cultures are negative and the clinical course subsequently indicates that the illness was not infectious, the antimicrobial regimen is stopped. Because of concern over respiratory signs as a part of the initial presentation of sepsis and the rapid progression of bacterial pneumonia in neonates with associated high mortality rate, particularly pneumonia caused by GBS, early and aggressive therapy is warranted in infants with respiratory distress syndrome.

Antibiotics are only part of the management of the newborn with pneumonia; supportive measures such as maintaining fluid and electrolyte balance, providing oxygen or support of respiration with continuous positive airway pressure, or instituting intubation and ventilation are equally important. Drainage of pleural effusions may be necessary when the accumulation of fluid results in respiratory embarrassment. Single or multiple thoracocenteses may be adequate when the volumes of fluid are small. If larger amounts are present, a closed drainage system with a chest tube may be needed. The tube should be removed as soon as its drainage function is completed because delay may result in injury to local tissues, secondary infection, and sinus formation. Empyema and abscess formation are uncommon but serious complications of pneumonia. They may occur in association with pneumonia caused by *S. aureus* and are discussed in detail in Chapter 14.

## PROGNOSIS

Available data on the significance of pneumonia during early life have been obtained in large measure from autopsy studies. There is information about the natural course of pneumonia caused by *S. aureus* in infants (see Chapter 14), but few studies of the sequelae of pneumonia caused by other agents exist. Even autopsy studies are equivocal in determining the importance of pneumonia because respiratory disease may have been the cause of death, a contributing factor in death, or incidental to and apart from the main cause of death [250,251]. Pneumonia was said to be the sole cause of death in about 15% of neonatal deaths studied by Ahvenainen [170]. In the British Perinatal Mortality Study [252], pulmonary infections were considered to be the cause of death in 5.5% of stillborn infants and infants dying in the neonatal period.

Ahvenainen [170] noted that pneumonia often is a fatal complicating factor in infants with certain underlying conditions, such as central nervous system malformations or disease, congenital heart disease, and anomalies of the gastrointestinal tract such as intestinal atresia. A prospective study of premature newborns found ventilator-associated pneumonia to occur frequently and to be significantly associated with death in extremely premature infants who remained in a neonatal intensive care unit for more than 30 days [253].

The presence of pneumonia in the neonatal period has been implicated as a cause of chronic pulmonary disease in infancy and childhood. Pacifico and associates [254] found that isolation of *U. urealyticum* from the respiratory tract of premature low birth weight infants in the first 7 days of life was associated with early development of bronchopulmonary dysplasia and severe pulmonary outcome. Brasfield and colleagues [255] studied a group of 205 infants hospitalized with pneumonitis during the first 3 months of life and identified radiographic and pulmonary function abnormalities that persisted for more than 1 year.

CHAPTER 8

# Bacterial Infections of the Bones and Joints

**Gary D. Overturf**

CHAPTER OUTLINE

## OSTEOMYELITIS

Osteomyelitis occurring in the first 2 months of life is uncommon. During the worldwide pandemic of staphylococcal disease from the early 1950s to the early 1960s, pediatric centers in Europe [1–5], Australia [6], and North America [6–11] reported the infrequent occurrence of neonatal osteomyelitis, accounting for only one or two admissions per year at each institution. With the introduction of invasive neonatal supportive care and the increased use of diagnostic and therapeutic procedures, there was concern that osteomyelitis and septic arthritis secondary to bacteremia might occur more frequently in the newborn [12]. Yet subsequent experience in Europe [13–15], Canada [16,17], and the United States [11,18,19] (Nelson JD, personal communication, 1987) during the decade 1970-1979 indicated little or no change in the incidence of this condition. Even in intensive care nurseries, despite an increasing problem with fungal (*Candida*) osteoarthritis [20–24], the overall rate of occurrence of nosocomial bone and joint infections remained low at equal to or less than 2.6 per 1000 admissions [22,25,26]. Infections associated with invasive procedures, such as placement of intravascular catheters, may not appear or be recognized until days or weeks after the perinatal period, however [12,22]. Although the incidence has not changed, causative organisms have become increasingly resistant to antibiotics, as exemplified by the increased incidence of *Staphylococcus aureus* infections resistant to oxacillin (methicillin-resistant *S. aureus* [MRSA]).

DOI: 10.1016/B978-1-4160-6400-8.00008-0

Little has been published on the relative incidence of neonatal osteomyelitis during the 1980s and 1990s. An ongoing review of nursery infections at a Kaiser Permanente hospital in southern California revealed only 3 cases of osteomyelitis among 67,000 consecutive live births from 1963-1993, and none occurred in the final years (Miller A, personal communication, 1993). A similar survey performed at two pediatric referral centers in Texas showed no significant variation in the number of annual admissions for this condition from 1964-1986[27] (Nelson JD, personal communication, 1987). Physicians working in intensive care nurseries in Great Britain [28], France [29], Spain [30], and various parts of the United States [31] (Pomerance J [Los Angeles, CA], Bradley JS [Portland, OR], Hall RT [Kansas City, MO], Cashore WJ [Providence, RI], personal communications, 1987) have observed, on average, 1 to 3 cases of bone or joint infection per 1000 admissions, an incidence almost identical to that noted in years past [22,25,26].

In a review of more than 300 cases of neonatal osteomyelitis, male infants predominated over female infants (1.6:1). Premature infants acquire osteomyelitis with relatively greater frequency than term infants [11,13,16,32–41]. In a series of osteomyelitis, 17 of 30 proven cases were in premature infants, 4 occurred in term infants receiving intensive care, and *S. aureus* was responsible for 23 of the proven cases of osteomyelitis (methicillin-sensitive strains in 16 cases and MRSA in 7 cases) [42]. *Escherichia coli* and group B streptococci (GBS) caused three and two cases, respectively. Risk factors for osteomyelitis and septic arthritis in premature infants have been mostly iatrogenic, including use of intravenous or intra-arterial catheters, ventilatory support, and bacteremia with nosocomial pathogens.

Although osteomyelitis was rare in the past, more recent series have suggested that the frequency may be increasing in neonates. The spectrum of bacterial and fungal infections in Finland from 1985-1989 was studied in 2836 infections in children [43]. The incidence of osteomyelitis and septic arthritis in children 28 days of age or younger was 67.7 per 100,000 person-years compared with rates of 262.2 and 2013.1 per 100,000 for meningitis and bacteremia; pneumonia (80.4 per 100,000) and pyelonephritis (143.8 per 100,000) also were more frequent than bone or joint infections. Studies from other countries have also suggested an increase in osteomyelitis; among 241 bone infections in Panamanian children, 9 occurred in neonates (3 cases were due to gram-negative bacilli; 3 cases, to *S. aureus*; 1 case, to GBS; and 2 cases, to other organisms) [44].

## MICROBIOLOGY

Because most cases of neonatal osteomyelitis arise as a consequence of bacteremia, the organisms responsible for causing osteomyelitis reflect the changing trends in the etiology of neonatal sepsis. Before 1940, hemolytic streptococci were the predominant organisms responsible for sepsis in newborns [45] and frequently caused osteomyelitis [46,47]. Streptococci were implicated in most cases of osteomyelitis in neonates and infants younger than 6 months of age [48].

After 1950, the incidence of *S. aureus* osteomyelitis increased. A review of reports from 1952-1972 showed that 85% of the infections were caused by *S. aureus*, 6% were caused by hemolytic streptococci (no groups specified), and 2% were due to *Streptococcus pneumoniae*; either no organisms or miscellaneous organisms (particularly gram-negative bacilli) were isolated in 7% of the cases [2–6,11,35,38,49–56]. MRSA has infected many nurseries and has been associated with disseminated infections of neonates, including endocarditis, skin and soft tissue infections, organ abscesses, and osteomyelitis and septic arthritis. Community-acquired strains of MRSA have become increasingly more common in neonatal units; at the present time, 50% or more of infections are caused by MRSA strains acquired outside of the hospital. Osteomyelitis and septic arthritis have been observed in these outbreaks as part of a general septic dissemination of MRSA to multiple organs and multiple sites (reviewed in Chapters 10 and 14).

Recognition of group B streptococcal sepsis in the 1970s was associated with a concomitant increase in reported frequency of bone and joint infections caused by this organism [20,57]. This change in spectrum was reflected in U.S. reviews of osteomyelitis in infants hospitalized from 1965-1978 showing that GBS had become the most frequent agent [11,19,58]. This experience was not universal, however; newborn centers in Canada [16], Sweden [13], Spain [30], Switzerland [14], Nigeria [59], and sections of the United States [27] continued to find *S. aureus* as the predominant cause of osteomyelitis, with GBS accounting for only a few cases. Although their relative importance may vary by region or institution, these two organisms have remained the most common cause of neonatal osteomyelitis [31–33,40]. A review of cases of occult bacteremia owing to GBS identified 147 children [60]. Eleven of these children had nonmeningeal foci, including two with septic arthritis and two with osteomyelitis. More recent cases of unusual sites of group B streptococcal osteomyelitis in the iliac wing [61] and the vertebrae [62] emphasize the renewed importance and frequency of this infection.

Osteomyelitis caused by gram-negative enteric bacilli is uncommon despite the frequency of neonatal bacteremia [32,45,63,64]. In Stockholm during 1969-1979, *E. coli* and *Klebsiella-Enterobacter* were responsible for about 30% of cases of neonatal septicemia [15], but only 5% of bone infections [13]. *S. aureus*, although also causing about 30% of neonatal bacteremia cases, was responsible for 75% of cases of osteomyelitis. Several other surveys performed within the past 2 decades show about 10% of cases of neonatal osteomyelitis to be due to gram-negative enteric bacilli,* although rates of 19% [59] and 45% [30,39,40] have been observed. A review of the literature has revealed isolated instances of hematogenous osteomyelitis in newborns caused by *E. coli*,† *Proteus* species [13,19,28,53,65–69], *Klebsiella pneumoniae* [13,30,40,41,70–73], *Enterobacter* [30,66,74,75], *Serratia marcescens* [19,30], *Pseudomonas* species,‡ and *Salmonella* [16,27,39,77–81].

‡References [19,30,35,38,40,47,76,77].

Although bacteremia from infected invasive devices are a common cause of enteric osteomyelitis, infection may occur directly by translocation from the gut or from urinary tract infection. Studies of neonatal rats have suggested that formula feeding enhances translocation of enteric organisms with subsequent infection of the bone [82], although other organs were infected as well. Although translocation of bacteria occurred in 23% of breast-fed rats, compared with 100% of formula-fed rats, positive bone cultures developed in 77% of the formula-fed rats, whereas none of the breast-fed rats had positive cultures. A single case of a 4-week-old boy with urinary tract infection with *K. pneumoniae* and vesicoureteral reflux suggests that this site also may be a source of gram-negative enteric bone and joint infections [83].
